The control of biochemical reactions by genes appears to be a widespread phenomenon.[1] There is already much evidence that, at least for certain species, the development of resistance to a given antibiotic by a strain (clone) of bacteria is due to spontaneous variation, which is heritable. It may be that several genes control the particular biochemical process, or processes, affected by penicillin: for the development of penicillin resistance by a sensitive strain of staphylococcus appears to be built up in the cells through an accumulation of successive mutations each leading to a higher degree of fastness.[2] Mutants possessing some degree of resistance tend to be selected during penicillin treatment, and, being relatively stable, may spread from individual to individual.[3] With a less perfect antibiotic such as streptomycin, highly insensitive strains not infrequently appear early, particularly in heavy infections. This suggests—and the idea is supported by some experimental evidence[4]—that genes of greatly differing potency cover the metabolic pathways blocked by streptomycin, and that a high degree of resistance may result from the mutation of a single potent gene.

In order to prevent the multiplication of these insensitive variants, some other antibacterial substance acting on a different enzyme system should be given simultaneously with streptomycin.[5] The justification for combined antibacterial therapy is this: that the chance of a mutant arising which is insensitive to 2 such antibacterial substances is the *product* of the frequency of their appearance to each substance separately. Since mutants resistant to a single antibacterial substance are relatively rare—in the order of 1 per 10 million cell divisions—the appearance of a mutant resistant to the combined action of 3 antibacterial substances, each possessing distinctive points of attack, is infinitesimal.

These considerations apply particularly to streptomycin when it is used to control infections due to relatively non-exacting strains with wide synthetic ability, such as *Pseudomonas pyocyanea* and *Bact. coli.*[6]

While the above explanation is admittedly controversial, and other more Lamarckian opinions are possible,[7] it does provide a rational account of drug resistance and removes from combined treatment the stigma of blunderbuss therapy. All this is, of course, apart from any synergism which may result from combined therapy, such as is presumably the reason for the better results obtained when a mixture of sulphonamides is substituted for the single drug.

In the future, no doubt, more attention will be paid to those antibiotics which affect metabolic pathways controlled by genes of low potency; 'Aureomycin'

In England Now

A Running Commentary by Peripatetic Correspondents

THE amount of interest the general election raised in the United States was quite surprising. In our hospital even the janitors and elevator girls asked me if I thought the Socialists would be returned. When I gave my usual answer "yes," and added. "with a majority of about 20 seats," there was usually some expression of mild disappointment. Many Americans given to thinking, and certainly talking, in extremes seem to believe Socialism is akin to Communism and they cannot understand why the "freedom-loving British nation" tolerates such an awful political system. Most of the papers rather hoped for a Conservative victory and kept picking out any signs of improvement in the Conservative cause. Mr. Churchill being an almost legendary hero here, all his speeches were given very full "coverage" and often editorial comment as well. The Government was berated for not doing more to further the aims of Mr. Hoffman, and the old story of U.S. dollars subsidising free wigs under the National Health Service was often repeated. Results began to come through on the radio about 6 P.M. E.S.T., and it was amusing to turn from station to station to hear different news commentators reading the same results and phrases as reported by Associated Press. Just as you thought you were going to learn further details the announcer would say *in his most dramatic voice*: "Men, have you shaved today? If not, use *Beatabeard*, the only all-dry, non-brush, non-razor, non-soap preparation that removes your beard in a flash"; or "The time is now 6.13 and a half, by courtesy of Dr. A. B. Twister, Kalamazoo's leading homœopathic physician." Some stations arranged discussions between political commentators in New York, Washington, Chicago, and London, while others transmitted on-the-spot interviews with members of the major parties and voters. The tremendous interest in the Royal Family was illustrated by the frequent references to the King, unlike the President, having no vote, and to a description of how Princess Elizabeth had "*driven round to Buckingham Palace to hear the results with Mom and Dad*" (sic). As Labour's early lead increased, commentators began to stress the importance of the popular vote, which showed a Conservative lead: later their commentaries changed as much as the lead in the election. Once or twice there was a transmission from the B.B.C., when an extraordinarily English voice would enunciate the results with great precision and apparently considerable boredom.

The friends with whom I listened to the results were staunch Republicans who had been overjoyed at the result in the New Zealand and Australian elections. Their faces got longer and longer as Labour increased its lead during the night, but they were not really any happier when the final result was known, since they recognised that any further progress in Europe can only come when there is a stable Government in Britain. They could not understand why the English should give up counting votes at 9 P.M. to go home to bed: this, more than anything else, proved to them that the English, whatever their tribulations and whatever their government, had not lost their essential character and sang-froid.

The only worth-while comment that I heard next day in the hospital was at lunch, when a Texan drawled: "*Guess you called the play O.K. on your election, doc.*"

* * *

Locke's Beloved Vagabond assured Asticot, apropos of certain deprivations and inconveniences, that there were a devil of a lot of things we can do without. This we were all compelled to appreciate in the war and to a not inconsiderable extent in the subsequent years. I am tempted to extend Paragot's philosophy about material things to our physical requirements.

One of our patients was the unfortunate possessor of a bizarre blood-group, so the rather haphazard if conventional transfusions he received for hæmatemesis had led to complete anuria. My highly efficient registrar and H.P. got busy. He was soon enjoying a nutritious if monotonous and unappetising menu of 400 g. of glucose, 100 g. of peanut oil with acacia to emulsify it, and rather less than a litre of water continuously administered by intragastric drip—all very scientific, proving that it is possible to sustain a man completely devoid of renal function.

The surgeons are boldly extending their activities to eliminate not only apparent superfluities but structures which we had believed to be necessities. For centuries the field was restricted to the foreskin. Well, that is just a cuticular redundance. Next the appendix, accepted as a vestigial structure and a source of trouble. Then came the colectomists, who tried for a time to persuade us that we were best without this cause of all evils. Thyroidectomy, splenectomy, and total gastrectomy followed, to show still further what we can do without, though we presumed that their functions were vicariously supplied, that there were, so to speak, spare parts. Portions of the sympathetic nervous system are now removed without apparent disadvantage; and so far from deploring the loss of areas of the brain, it is even claimed that we may be all the better for the confiscation. To pneumonectomy we were reconciled on the principle that half a loaf is better than no bread, especially as with Drinker's apparatus and adequate oxygen we are in fact independent of breathing at all.

One can go even further than merely delegating the function of our ablated organs or systems to those that remain. Artificial insemination has demonstrated another aspect of supplementing or displacing a natural process.

Yes, as Paragot said, there are a devil of a lot of things we can do without. Time will show to what extent we are as well off or better without them and will demonstrate in due course the irreducible minimum for existence.

* * *

It is one of our minor social hypocrisies that we all like what we call "a good cup of tea" but that none of us will admit liking it *strong*. Idiosyncrasies we will own to—a preference for tea with sugar or without, with milk or lemon or neither—though there are those breezy unfastidious souls who reply briskly to their hostess's inquiry, "Just as it comes, please." But the good lady would probably drop the teapot a-clatter among the cups and saucers if anyone asked boldly for STRONG TEA; it is more manly, and almost more respectable, to profess an addiction to strong drink.

Doctors are largely to blame for this semi-moralistic attitude, so long have we preached about tannin-coated gastric mucosa and ruined nerves. The Briton's habitual melancholia also plays a part; he regards as sinful anything that he enjoys, and when sin is out of fashion he gets dyspepsia instead. He must needs suffer as he sips, consoling himself the while by eyeing some other fellow's brew and murmuring pharisaically, "My God, I couldn't drink my tea as strong as *that*!"

But what is the standard—what *is* the right strength for a cup of tea? The question seems as unanswerable as the famous one about the length of a piece of string.

* * *

Barkis may have gone out with the tide, but zero hour for our family is certainly 4.30–7 P.M. After tea the kids demand to be entertained; and even if the television does provide an alternative on Sundays, they will not look at the beastly thing alone, holding it to be closely related to ghosts. Then there is the back-breaking job of putting them to bed, a process spun out by every diabolical form of ingenuity known to the infantile mind. Next comes the story to be read—less odious since they discovered Dr. Dolittle and *What Katy Did*. Finally, their Fabian tactics over having the lights put out are masterly: "Just one more hug, Mummy"; "Do kiss me, Daddy—Oh! your whiskers—let me find a bit that isn't whiskery," and so on. We start supper vowing that procreation is the greatest of all human follies. Then as our blood-sugars rise, so do our spirits. Zero hour is past once more and if we can't be said, at our age, to face the evening with renewed vigour, at least we do face it.

* * *

Dear, dear! *Surely anyone can see that the solution to the 20-foot ladder problem of March 11 is:*

$$2\left[\sqrt{26}-1+\sqrt{23-2\sqrt{26}}\right]+4=19{\cdot}35 \text{ feet.}$$

office. We have all got used to this, and it does not interfere in the slightest with one's work. It is important to put the staple at least $^1/_4$ in. from the edge of the swab lest it pull off.

The accompanying illustrations show the swab, and also an X-ray picture, taken through an obese abdomen, a swab applied to the opposite side. The staple shows quite clearly, and were it in the abdomen I am told it would show even more clearly. Recently such a swab was inadvertently left in a limb after an operation for osteomyelitis, but its presence was detected by X rays and it was removed.

The advantages of this method are cheapness and the availability of the materials that exist in every hospital office. It is in the hope of diminishing the anxiety of my colleagues and of theatre sisters that I publish this simple method.

Hove, Sussex. H. J. McCURRICH.

ODD FEET

SIR,—I can endorse the suggestion, in your annotation last week, that odd shoes should be made available to the public. There used to be an odd-shoe shop near Guy's Hospital. Many normal people have feet differing by as much as one size.

There is a more serious problem. It is well known that many minor disabilities of the foot are caused by wearing short shoes during the growing period of life. Often when I have recommended shoes of a particular size for a child—usually a girl—I have later found that she has been sold a size shorter than marked. Some unscrupulous shoe manufacturers mark their ladies' shoes a size larger than they measure. There should be a law making it compulsory for the shoe manufacturer to stamp the correct size on the shoe in the same way that the weight of contents of a tin or package must be stated accurately.

My plea is based on sixteen years' experience at the Luton clinic, where about a thousand children a year are referred to me. Such a statute would save many a working mother the cost of a useless pair of shoes.

London, W.1. DAVID LEVI.

TRICHLORETHYLENE IN OBSTETRICS

SIR,—Dr. Steel raises some interesting points in his letter of March 4. I entirely agree with him that the relief obtained by self-administered intermittent inhalation analgesia is largely determined by the quality of the supervision, both before and during labour. But surely a fixed upper limit of trichlorethylene concentration is necessary in the interests of safety? If this fixed concentration is adequate for delivery, it will be more than adequate for a less painful stimulus, but does this matter? I have not seen any labouring woman acquire tolerance during labour to an effective analgesic drug. I have always thought that tolerance is only acquired after weeks or months of administration. Self-administered inhalation analgesia becomes a burden if protracted, and then loses its value.

The effect of trichlorethylene is cumulative because its elimination is slow, but my experience is that 0·5% trichlorethylene in air can be used in labour for periods up to six hours before the mother becomes drowsy. When used for longer than this, the mother does become drowsy, and I agree with Dr. Steel that the uterine action may, occasionally, become sluggish. In almost all labours supervised by midwives, however, intermittent inhalation is needed for periods less than five hours, and I see no reason why a vapour which is adequate for the end of the first stage and for delivery should not be used throughout.

Oxford. E. H. SEWARD.

CROHN'S DISEASE

SIR,—The Disabilities article by a doctor, in your issue of Feb. 11, is a valuable contribution to the literature on Crohn's disease, and it emphasises several points which are not generally appreciated. To us the account was of particular interest because we have just completed a follow-up investigation of 34 cases treated, at the General Infirmary at Leeds during the past fifteen years, an account of which will shortly appear in the *British Journal of Surgery*. The case described might well be one of our series, so similar are the two cases.

A one-stage right hemicolectomy is believed to be the treatment of choice in uncomplicated cases, but it is not by any means 100% curative. In 20 of our cases a one-stage right hemicolectomy was carried out with no deaths, but recurrence took place in 4—i.e., 20%. Bockus[1] states that good results are probably not to be anticipated in more than 50% of resections. The interval between resection and recurrence of symptoms varied widely in our 4 cases, where it was $12^1/_2$ years, 5 years, 4 years, and one month, respectively. In each case pain was the prominent symptom; loss of weight, anæmia, and looseness of the bowels were present but were of quite subsidiary importance. In one case the appearance of a palpable glandular mass in the right iliac fossa seven years after the primary resection indicated at the outset the need for a wide glandular removal.

GEORGE ARMITAGE
Leeds. MICHAEL WILSON.

DEOXYCORTONE ACETATE AND ASCORBIC ACID IN ANKYLOSING SPONDYLITIS

SIR,—I have used the method reported by Lewin and Wassén[2] in cases of acute and chronic rheumatoid arthritis with the varying results recorded by subsequent investigators.

Most pronounced and surprising was the beneficial effect of this treatment in two cases of Bechterew's disease. The duration of the illnesses was 12 and 13 years. Radiologically both patients were shown to have severe ankylosing changes of the vertebral column:

> About 15 minutes after the first injection, one patient was able to move the head in all directions and to bend his back, which had been completely rigid; and during the next two hours mobility increased still further. After the second injection he was able to lie down quickly and to get up from the floor, to take off and put on his clothes (which previously had been possible only with the help of others), to lift and rotate his legs and arms, &c. The effect of the second injection lasted for 48 hours. The patient, who was an ardent tennis-player before the onset of the disease, felt as though he "might start playing again."
>
> The second patient, who complained particularly of complete stiffness of the neck, responded less dramatically than the first. Yet 15 minutes after the first injection he turned his head about 25° to each side, and after approximately one hour he managed to move it slightly forwards and backwards. After another half-hour the mobility of the thoracic and lumbar spine also increased somewhat.

I recalled having treated arthritic changes by ovarian transplants about twenty-five years ago. I wrote at that time[3]: "In einigen Fallen unseres Beobachtungsmaterials brachte Transplantation eines jugendlichen Ovars überraschenden Erfolg." (In some of our cases transplantation of a juvenile ovary led to surprisingly good results.) Accordingly I administered œstrogenic hormone (50,000 units) and 5 minutes later vitamin C (1 g.) intravenously to some female patients suffering from rheumatoid arthritis; there was either no response or at best a slight response. Progesterone (5 mg.)

may well be such a one. But at present, while the new antibiotics are still under trial, there are sound reasons for supporting Professor Long's plea that a combination of drugs should more frequently be used from the start (and not after one or two failures) in bacterial infections where resistance to drugs is known to arise readily.

Llandaff, near Cardiff. A. C. T. VAUGHAN.

ARTERIAL CALCIFICATION

SIR,—We have read with interest the article of March 4 by Sir Adolphe Abrahams.

In the course of a study which we are making of calcification elsewhere in the body, we have taken X-ray pictures of the calves of 69 men over the age of sixty, none of whom had any symptoms of intermittent claudication. We also examined them and palpated the dorsalis pedis and posterior tibial arteries. Dividing our cases into those with and those without calcification of the tibial arteries, we found that in the calcification group (29 cases) all the foot arteries were palpable in 13, while none was felt in 4; in the non-calcification group (40 cases) the figures were 21 and 5, respectively. That is, the proportions are roughly the same for both groups.

Thus, calcification has no relation to arterial patency, as judged by palpation of the foot arteries, and it can certainly be extensive in the absence of symptoms.

HEALTH CENTRES

SIR,—Lurking in the obscurities of the local press are occasional jewels of revelation. The *Hampstead and Highgate Observer* (Jan. 26) recently reported Mr. Reginald Stamp, chairman of the L.C.C. health committee, as saying that the Minister of Health had agreed to nine health centres being built in London—" but the doctors would not come in," said Mr. Stamp. His remarks have now been gently and firmly corrected by the Secretary of the Local Medical Committee for London, who has pointed out (*Ibid*, Feb. 10) that " many doctors are perfectly willing to enter health centres when the details have been worked out. In London alone 29 groups of doctors have asked the L.C.C. to find health centre premises for them to work in."

This answer, by Dr. Gray, would be less forceful but more accurate if he had said " *only* 29 groups." Mr. Stamp is certainly wide of the mark, and one wonders whether his lame excuses were made for want of better ones. Nevertheless as long as the profession is so uninterested in a measure so vital for the nation's health, Mr. Stamp may succeed in throwing the blame for the failure to build health centres on to the shoulders of the medical profession, which, as every schoolboy knows, directs the financial policies of the Government and acts as bricklayers' labourers in its spare time.

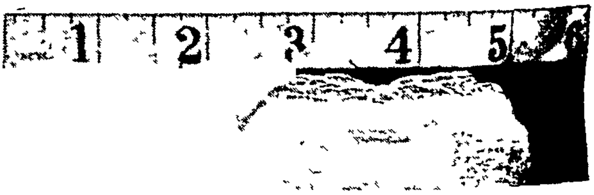
Mr. Bevan has called the health centre " the pivot of the health service " ; yet no attempt has been made to encourage the profession as a whole and more particularly the general practitioners, who will have to staff and run the centres, when they are built, to voice their opinions and their difficulties on the widest scale possible. The B.M.A. has a health centre committee which has recently reported favourably on the introduction of group practice from health centres, but is now being forced by present economic difficulties to consider other means of grouping in general practice. Nowhere do we find the inspiration and the foresight among the senior members of the profession which not merely acknowledges the inevitability of health centres but organises medical opinion so that we can overcome the difficulties before they arise, and can even exert some very desirable pressure on the Minister to keep his promises. Alas ! we may not be the oldest profession, but we seem to be the most backward.

The health centre must be the centre of attraction locally not only for the man in the street, but also for the doctor. Local committees of doctors and laymen should be constituted now by any responsible organisations—the local authorities, who are responsible for building the health centres, might reasonably sponsor such a movement. Most important is the dissemination of knowledge and the firing of the doctors' enthusiasm for this most fundamentally important weapon of medical progress. When the time comes for further excuses we might then expect an answer of a different Stamp.

London, S.W.17. DAVID L. KERR.

THE FORGOTTEN SWAB

SIR,—The forgotten swab is a lurking nightmare of every surgeon and theatre sister. As Sister Kent (March 4) writes, sudden and unexpected hæmorrhage in a deep and inaccessible cavity may cause the surgeon to pack a small swab down on to the bleeding vessel; finding this stops the hæmorrhage he leaves it there, intending to remove it later when the bleeding may not recur. In the meantime he carries on with the operation, but possibly after a long and difficult procedure he forgets about the swab. Swab counts are not always correct, and sometimes a prolonged search fails to produce an alleged lost swab. This leads to an anxious feeling of uncertainty.



Various methods have been devised to render swabs traceable by X rays, such as the metal thread referred to by Miss Alexander (Feb. 25). Being unable to get special gadgets I devised a simple method. The theatre sister, Sister Shaw, of the Royal Sussex County Hospital, inserts into each gauze swab a small metal staple with a little press for clipping letters which we got from the

office. We have all got used to this, and it does not interfere in the slightest with one's work. It is important to put the staple at least 1/4 in. from the edge of the swab lest it pull off.

The accompanying illustrations show the swab, and also an X-ray picture, taken through an obese abdomen, a swab applied to the opposite side. The staple shows quite clearly, and were it in the abdomen I am told it would show even more clearly. Recently such a swab was inadvertently left in a limb after an operation for osteomyelitis, but its presence was detected by X rays and it was removed.

The advantages of this method are cheapness and the availability of the materials that exist in every hospital office. It is in the hope of diminishing the anxiety of my colleagues and of theatre sisters that I publish this simple method.

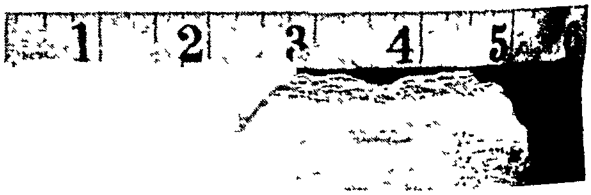
Alas! we may not be the oldest profession, but we seem to be the most backward.

The health centre must be the centre of attraction locally not only for the man in the street, but also for the doctor. Local committees of doctors and laymen should be constituted now by any responsible organisations—the local authorities, who are responsible for building the health centres, might reasonably sponsor such a movement. Most important is the dissemination of knowledge and the firing of the doctors' enthusiasm for this most fundamentally important weapon of medical progress. When the time comes for further excuses we might then expect an answer of a different Stamp.

London, S.W.17. DAVID L. KERR.

THE FORGOTTEN SWAB

SIR,—The forgotten swab is a lurking nightmare of every surgeon and theatre sister. As Sister Kent (March 4) writes, sudden and unexpected hæmorrhage in a deep and inaccessible cavity may cause the surgeon to pack a small swab down on to the bleeding vessel; finding this stops the hæmorrhage he leaves it there, intending to remove it later when the bleeding may not recur. In the meantime he carries on with the operation, but possibly after a long and difficult procedure he forgets about the swab. Swab counts are not always correct, and sometimes a prolonged search fails to produce an alleged lost swab. This leads to an anxious feeling of uncertainty.



Various methods have been devised to render swabs traceable by X rays, such as the metal thread referred to by Miss Alexander (Feb. 25). Being unable to get special gadgets I devised a simple method. The theatre sister, Sister Shaw, of the Royal Sussex County Hospital, inserts into each gauze swab a small metal staple with a little press for clipping letters which we got from the

office. We have all got used to this, and it does not interfere in the slightest with one's work. It is important to put the staple at least ${}^1/_4$ in. from the edge of the swab lest it pull off.

The accompanying illustrations show the swab, and also an X-ray picture, taken through an obese abdomen, a swab applied to the opposite side. The staple shows quite clearly, and were it in the abdomen I am told it would show even more clearly. Recently such a swab was inadvertently left in a limb after an operation for osteomyelitis, but its presence was detected by X rays and it was removed.

The advantages of this method are cheapness and the availability of the materials that exist in every hospital office. It is in the hope of diminishing the anxiety of my colleagues and of theatre sisters that I publish this simple method.

Hove, Sussex. H. J. McCURRICH.

ODD FEET

SIR,—I can endorse the suggestion, in your annotation last week, that odd shoes should be made available to the public. There used to be an odd-shoe shop near Guy's Hospital. Many normal people have feet differing by as much as one size.

There is a more serious problem. It is well known that many minor disabilities of the foot are caused by wearing short shoes during the growing period of life. Often when I have recommended shoes of a particular size for a child—usually a girl—I have later found that she has been sold a size shorter than marked. Some unscrupulous shoe manufacturers mark their ladies' shoes a size larger than they measure. There should be a law making it compulsory for the shoe manufacturer to stamp the correct size on the shoe in the same way that the weight of contents of a tin or package must be stated accurately.

My plea is based on sixteen years' experience at the Luton clinic, where about a thousand children a year are referred to me. Such a statute would save many a working mother the cost of a useless pair of shoes.

London, W.1. DAVID LEVI.

TRICHLORETHYLENE IN OBSTETRICS

SIR,—Dr. Steel raises some interesting points in his letter of March 4. I entirely agree with him that the relief obtained by self-administered intermittent inhalation analgesia is largely determined by the quality of the supervision, both before and during labour. But surely a fixed upper limit of trichlorethylene concentration is necessary in the interests of safety? If this fixed concentration is adequate for delivery, it will be more than adequate for a less painful stimulus, but does this matter? I have not seen any labouring woman acquire tolerance during labour to an effective analgesic drug. I have always thought that tolerance is only acquired after weeks or months of administration. Self-administered inhalation analgesia becomes a burden if protracted, and then loses its value.

The effect of trichlorethylene is cumulative because its elimination is slow, but my experience is that 0·5% trichlorethylene in air can be used in labour for periods up to six hours before the mother becomes drowsy. When used for longer than this, the mother does become drowsy, and I agree with Dr. Steel that the uterine action may, occasionally, become sluggish. In almost all labours supervised by midwives, however, intermittent inhalation is needed for periods less than five hours, and I see no reason why a vapour which is adequate for the end of the first stage and for delivery should not be used throughout.

Oxford. E. H. SEWARD.

CROHN'S DISEASE

SIR,—The Disabilities article by a doctor, in your issue of Feb. 11, is a valuable contribution to the literature on Crohn's disease, and it emphasises several points which are not generally appreciated. To us the account was of particular interest because we have just completed a follow-up investigation of 34 cases treated at the General Infirmary at Leeds during the past fifteen years, an account of which will shortly appear in the *British Journal of Surgery*. The case described might well be one of our series, so similar are the two cases.

A one-stage right hemicolectomy is believed to be the treatment of choice in uncomplicated cases, but it is not by any means 100% curative. In 20 of our cases a one-stage right hemicolectomy was carried out with no deaths, but recurrence took place in 4—i.e., 20%. Bockus [1] states that good results are probably not to be anticipated in more than 50% of resections. The interval between resection and recurrence of symptoms varied widely in our 4 cases, where it was $12^1/_2$ years, 5 years, 4 years, and one month, respectively. In each case pain was the prominent symptom: loss of weight, anæmia, and looseness of the bowels were present but were of quite subsidiary importance. In one case the appearance of a palpable glandular mass in the right iliac fossa seven years after the primary resection indicated at the outset the need for a wide glandular removal.

GEORGE ARMITAGE
Leeds. MICHAEL WILSON.

DEOXYCORTONE ACETATE AND ASCORBIC ACID IN ANKYLOSING SPONDYLITIS

SIR,—I have used the method reported by Lewin and Wassén [2] in cases of acute and chronic rheumatoid arthritis with the varying results recorded by subsequent investigators.

Most pronounced and surprising was the beneficial effect of this treatment in two cases of Bechterew's disease. The duration of the illnesses was 12 and 13 years. Radiologically both patients were shown to have severe ankylosing changes of the vertebral column:

> About 15 minutes after the first injection, one patient was able to move the head in all directions and to bend his back, which had been completely rigid; and during the next two hours mobility increased still further. After the second injection he was able to lie down quickly and to get up from the floor, to take off and put on his clothes (which previously had been possible only with the help of others), to lift and rotate his legs and arms, &c. The effect of the second injection lasted for 48 hours. The patient, who was an ardent tennis-player before the onset of the disease, felt as though he "might start playing again."
>
> The second patient, who complained particularly of complete stiffness of the neck, responded less dramatically than the first. Yet 15 minutes after the first injection he turned his head about 25° to each side, and after approximately one hour he managed to move it slightly forwards and backwards. After another half-hour the mobility of the thoracic and lumbar spine also increased somewhat.

I recalled having treated arthritic changes by ovarian transplants about twenty-five years ago. I wrote at that time [3]: "In einigen Fällen unseres Beobachtungsmaterials brachte Transplantation eines jugendlichen Ovars überraschenden Erfolg." (In some of our cases transplantation of a juvenile ovary led to surprisingly good results.) Accordingly I administered œstrogenic hormone (50,000 units) and 5 minutes later vitamin C (1 g.) intravenously to some female patients suffering from rheumatoid arthritis; there was either no response or at best a slight response. Progesterone (5 mg.)

administered in the same way, however, produced in 3 cases the same favourable results as deoxycortone; in 1 case progesterone proved even more effective than deoxycortone.

These observations are intended to supplement the report of Landsberg [4] on the action of progesterone in such cases.

Jerusalem. HERMANN ZONDEK.

PERSONALITY AND NURSING

SIR,—The article by Mrs. Petrie and Miss Powell, which you published on Feb. 25, is an important contribution to a very difficult field. For almost the first time adequate attention has been paid to the criterion of just what constitutes a good nurse; for the first time personality tests other than the egregious questionnaire have been used; and for the first time the investigation appears to have been based on a definite hypothesis rather than consisting in the random administration of tests aimlessly thrown together.

The criticisms made by Dr. Hamilton last week deal largely with statistical minutiæ, which do not affect the broad results of the investigation. There appears to be no doubt that personality tests correlate significantly with success in nursing; it follows that tests of this type could, with advantage, be used as part of a carefully planned selection procedure. The particular figures given by Petrie and Powell are an exact description only of their findings and cannot in any case be generalised; as the authors themselves point out: "At other hospitals, where different conditions exist, the improvement in selection following upon the use of the tests will vary." It is to be hoped that other hospitals will take the opportunity created by the results of this pioneer study to test its conclusions for themselves.

DANGER FROM THE NEWER INSECTICIDES

SIR,—We were glad to note the timely warning, in your issue of March 4, about the dangers inherent in the indiscriminate use of the newer insecticides, including the phosphorus compounds. For many years we ourselves have been trying to impress upon farmers that the handling and application of such products requires a degree of skill and caution which is seldom found amongst agricultural workers.

In our organisation we have found that it takes several years to make spray operatives "safety-minded," and it is only by insisting on adequate protective measures that these materials can be applied with safety. These measures include the provision of protective clothing for spray crews, the use of air-conditioned spray-proof tractor cabs, and regular medical inspection of the operators, combined with strict supervision. Our own medical unit has carried out research for several years into the toxicology of these chemicals; and the safeguards which we employ go, in fact, considerably beyond the precautions advised by Dr. Hunter in the lecture which you quoted.

While we fully agree with the need for the warning which has been issued, we feel it would be undesirable if these products, with their great potentialities for increasing food production, should come into disrepute through careless and irresponsible usage. Farmers should, therefore, insist that when these materials are used on their farms proper medical supervision is available and adequate protective measures are taken.

PEST CONTROL (UNITED KINGDOM) LTD.

Bourn, Cambridge.

ADMISSIONS TO HOSPITAL

SIR,—I have read with interest the annotation under this heading in your issue of March 4.

The procedure recommended in respect of chronic sick waiting-lists has been in force in this neighbourhood for some time. A doctor from the hospital management committee keeps the waiting-list under constant review, and after making the necessary visits determines the order of admission, having regard to the comparative medical urgency of the cases.

This procedure, as you suggest, also curtails the waiting-list by diverting some of the cases to the appropriate domiciliary agencies or to the "Part III" accommodation provided by local authorities. It can be recommended to any hospital management committee having a lengthy waiting-list of chronic sick.

Bradford (B) Hospital
Management Committee.

ACTION OF ASCORBIC ACID ON DEOXYCORTONE

SIR,—Readers of my article of Feb. 25 (p. 351) have asked me to justify my opinion that in the treatment of rheumatoid arthritis with deoxycortone and ascorbic acid, by the method of Lewin and Wassén,[1] the ascorbic acid probably acts by oxidising the deoxycortone. It may seem paradoxical that ascorbic acid should have an oxidising effect since it is a reducing agent, and Brownlee [2] favours the view that the deoxycortone is reduced by the ascorbic acid. Huszak,[3] however, showed that hydrogen peroxide is formed on oxidation of ascorbic acid, and Ekman [4] demonstrated that, in vitro as well as in vivo, cyclic compounds are oxidised by ascorbic acid and that this may be explained by the formation of hydrogen peroxide.

Ekman also showed that Fe and Cu ions, among others, have a catalysing effect on the oxidation of cyclic compounds by ascorbic acid. Experiments are therefore being carried out to study the effects of the simultaneous addition of various likely catalysts besides deoxycortone and ascorbic acid. In addition, efforts are being made to synthesise the potent anti-rheumatic substance formed when combined injections of deoxycortone acetate and ascorbic acid are given.

County Hospital,
Örnsköldsvik, Sweden.

LEIF HALLBERG.

THE CARNAGE ON THE ROADS

SIR,—I was interested to read Dr. Learoyd's article of Feb. 25 and the subsequent correspondence.

Any suggestion that the majority of road accidents are due to ignorance of car manipulation, mechanical driving matters, and so forth does not go deep enough. I am of the opinion that it is not ignorance of these matters that causes accidents, but psychological faults which cannot be elicited by even more stringent driving tests. It is well known that there are certain people who are by nature particularly susceptible to accidents. It is estimated that about 10% of drivers are responsible for about 60% of accidents. The constellation of causes is made up of several factors; and, in the majority of cases, the psychological factor appears to be the most important. Accident-proneness tests yield significant correlation coefficients between the scores made and accident-rates. These tests would enable us to eliminate unsuitable people from those proposed as drivers. Of course, there are many other factors in the problem, such as alcohol, loss of sleep, fatigue, poor general health, domestic and business worries, and defective cars and roads.

[4] Ekman, B. *Acta physiol. scand.* 1944, 8, suppl. 22.

The publication—for the general public—of statistical tables showing age-groups and the category of road user primarily responsible for the accident would be interesting, and might bring home to all road users their responsibilities in these matters.

G. C. F. ROE
Halifax. Medical Officer of Health.

SIR,—May I ask Dr. Learoyd whether he has taken the trouble to find out from statistics who is responsible for most accidents? Is it really the beginner, or is it the reckless driver who cannot help racing along the road? Is it the private car or is it the lorry which has more victims to its account? Also, what is the condition of the car or lorry involved in fatal accidents? I think before suggesting more tests and so on, one should find out more details.

London, W.C.1. E. F. MEYER.

COLOUR TELEVISION

SIR,—Your report last week (p. 475) of the use of colour television for the demonstration of dental operations at Guy's Hospital prompts me to add a comment.

The same apparatus was used earlier in the same week at St. Thomas's Hospital, when a series of experiments were carried out with regard to its usefulness for teaching. Satisfactory pictures were obtained of the retina, and some operations on the eye were televised, with a commentary, to two monitor sets in a nearby room.

It is interesting to note that not alternate frames but alternate half-frames are transmitted in the three colours. Thus blue is interlaced with red, green with blue, and red with green. This tends to reduce the effect in which three different coloured images of a rapidly moving object are seen to follow one another across the screen—a fault common to all sequential-colour systems.

Newdigate, Surrey. W. F. WHEELER.

EXPERIMENTAL PRODUCTION OF MALIGNANT TUMOURS BY BERYLLIUM

SIR,—Your last issue contains an interesting letter from Dr. Barnes, in which he says he has repeated the experiments of Gardner and Herlington[1] and produced bone sarcomas in rabbits by intravenous injections of beryllium compounds. He remarks that this may possibly be another industrial hazard.

While working in the medical laboratories of the Collis P. Huntington Memorial Hospital of Harvard University in 1947–48, I, in collaboration with R. S. Grier and M. B. Hoagland, also confirmed this work, and the results have already been presented in thesis form.[2] We gave rabbits repeated intravenous injections of 1% suspensions of beryllium oxide and zinc beryllium silicate. Of 28 rabbits injected, 5 developed typical osteogenic sarcomas which disseminated widely. In one instance a successful transplant into the eye of a guineapig was made. The dose needed to produce these tumours is not accurately known, but one of our animals developed a sarcoma after receiving 200 mg. of zinc beryllium silicate over a period of two weeks. There was a delay from nine to nineteen months between giving the injections and the development of the sarcomas.

In some fatal cases of chronic berylliosis in the U.S.A. a certain amount of beryllium has been detected in the bones,[3] but histological examination of these has shown no sign of pathological change. It is reasonable to suppose that other workers who received an exposure to beryllium comparable to that of these fatal cases may also have some beryllium present in their bones. If this is so, the beryllium has by now been there for nearly ten years, but no ill effects have been reported.

Rabbits are the only animals in which these tumours have been produced, and I think we should be a little cautious about suggesting that they may arise in industrial workers.

WAR

SIR,—"Wars arise, and must continue to arise, in the minds of ordinary men." Since sociology began to be applied to the study of aggressive behaviour in group and community life, it has concentrated on the mechanisms which are to hand in daily experience—stereotypy, projection, fear of out-groups, and aggressive impulses in urban publics. This work is of great importance, and the part played by such processes in preparing the ground for war is beyond reasonable question. Dr. Ranyard West has discussed them in detail before[1]—he was among the first English writers to show a clear appreciation of the part which sociology must play in the abolition of war-promoting circumstances. But before it is possible to accept, as he accepts, the World Government idea as a form of therapy, there are several further observations which must be accommodated.

A study of the actual history of recent wars does not support an interpretation of them as outbursts of specific aggression at the individual level. Without the need to discharge such aggression they would probably not have occurred, but the view which identifies war with the individual grossly understates the part played by governments. There is reason to think that the worst acts of delinquency in recent international affairs have been without exception the work of individual psychopaths in office, carried out by enforcement élites indoctrinated for the purpose, or gradually inched into public acceptance by intensive propaganda. Spontaneous aggression has, as a rule, been limited to minor delinquency such as lynching, ill-treatment of aliens, or looting. However well established the stereotypy, it has great difficulty in surviving personal contact between populations, and in almost all cases where such contact occurred it led rapidly to fraternisation, sexual contacts, and loss of fighting spirit. The importance of individual aggression and irrational attitude has lain chiefly in providing a handle whereby the office-bearing psychopath can secure acquiescence. There is no contemporary instance of an aggressor State which has been able to dispense with conscription enforced by signal punishment for refusal. At least two examples of delinquent international behaviour of this kind, the German pogroms and the Allied policy of indiscriminate bombardment, are very fully documented. A recent writer on antisemitism[2] has pointed out that at the height of the Nazi campaign, "objective" antisemitism based on race friction was minimal compared with the "subjective" type, worked up from above. In England and America, the atomic bomb in particular was exclusively the work of the national leadership, and has produced extensive rationalisation and guilt-feelings in the publics concerned.

In view of the observed evidence, it seems that the causes which Dr. West has cited as primary, together with other, antecedent, cultural factors leading to undischarged aggression, such as those described by Mumford[3] and by Halliday[4] in urban civilisations, are in fact predisposing elements rather than prime causes of war. A far more important group of factors is associated with the presence of psychopaths in office, and with the conception of centralised power itself. There is a con-

WAR

SIR,—"Wars arise, and must continue to arise, in the minds of ordinary men." Since sociology began to be applied to the study of aggressive behaviour in group and community life, it has concentrated on the mechanisms which are to hand in daily experience—stereotypy, projection, fear of out-groups, and aggressive impulses in urban publics. This work is of great importance, and the part played by such processes in preparing the ground for war is beyond reasonable question. Dr. Ranyard West has discussed them in detail before[1]—he was among the first English writers to show a clear appreciation of the part which sociology must play in the abolition of war-promoting circumstances. But before it is possible to accept, as he accepts, the World Government idea as a form of therapy, there are several further observations which must be accommodated.

A study of the actual history of recent wars does not support an interpretation of them as outbursts of specific aggression at the individual level. Without the need to discharge such aggression they would probably not have occurred, but the view which identifies war with the individual grossly understates the part played by governments. There is reason to think that the worst acts of delinquency in recent international affairs have been without exception the work of individual psychopaths in office, carried out by enforcement élites indoctrinated for the purpose, or gradually inched into public acceptance by intensive propaganda. Spontaneous aggression has, as a rule, been limited to minor delinquency such as lynching, ill-treatment of aliens, or looting. However well established the stereotypy, it has great difficulty in surviving personal contact between populations, and in almost all cases where such contact occurred it led rapidly to fraternisation, sexual contacts, and loss of fighting spirit. The importance of individual aggression and irrational attitude has lain chiefly in providing a handle whereby the office-bearing psychopath can secure acquiescence. There is no contemporary instance of an aggressor State which has been able to dispense with conscription enforced by signal punishment for refusal. At least two examples of delinquent international behaviour of this kind, the German pogroms and the Allied policy of indiscriminate bombardment, are very fully documented. A recent writer on antisemitism[2] has pointed out that at the height of the Nazi campaign, "objective" antisemitism based on race friction was minimal compared with the "subjective" type, worked up from above. In England and America, the atomic bomb in particular was exclusively the work of the national leadership, and has produced extensive rationalisation and guilt-feelings in the publics concerned.

In view of the observed evidence, it seems that the causes which Dr. West has cited as primary, together with other, antecedent, cultural factors leading to undischarged aggression, such as those described by Mumford[3] and by Halliday[4] in urban civilisations, are in fact predisposing elements rather than prime causes of war. A far more important group of factors is associated with the presence of psychopaths in office, and with the conception of centralised power itself. There is a con-

2. Reichmann, E. G. Hostages of Civilisation. 1950.
3. Mumford, L. The Culture of Cities. 1935.
4. Halliday, J. L. Psychosocial Medicine. 1949.

siderable amount of evidence from anthropology, history, and psycho-analysis which relates the desire to exercise power to mental abnormality, or at least to personality deviation. Dr. West himself has already drawn attention to the singular convenience of political office as a platform for the "unconscious play-actor from childhood." While it is possible to classify primitive societies into power-centred and life-centred types, the first aggressive and repressive, the second largely coöperative and social, in larger cultures like our own it is more accurate to speak of power-centred and life-centred individuals. Centralised authority selects the former, and tends to exemplify the syndrome of "cruelty, chastity, and coercion" which has been identified in aggressive primitive societies. Many writers, from William Godwin to Riewald,[5] have drawn attention to the rôle of political office under modern conditions as an outlet for psychopathy, but a culture which possesses the political background of Western Europe does not take very readily to such a conception. At a time when the crimes imposed by governments manifestly eclipse those committed by individuals, and the orthodox notions of the function of coercion in maintaining sociality have been seriously undermined by innumerable studies of the non-coercive management of delinquents, it is distressing to find Dr. West still ready to accept the traditional concepts of the function of power at their face value.

This whole argument throws a very different light on the issue of world government. The idea of such a government is part of the tradition of the State as guarantor of rights by the exercise of coercion—a construct which, in the light of recent work, it seems very difficult to maintain. In any politically likely form, such a world authority would be recruited, as is UNO, from members of existing ruling groups—in other words, from a panel where the selection of deviants and power-centred individuals had already once taken place. Office in such a body would offer little incentive beyond that of still wider and still less responsible authority, and there seems no reason for the view that those who already show themselves dangerously delinquent in their present limited scope would become less so if it were to be made universal.

The conception of power as the force which renders us social is defunct upon every evidential consideration, and there is nothing to be gained by propping it into a sitting posture. While sociological action against false ways of group thought, on the lines of the Tensions Project, is an urgent need, there comes a point at which the duty of psychiatry lies in a direct appeal to the sociality of the individual. What we need today is not more government but more responsible and rational disobedience. The individual in his capacity of citizen is the tool whereby the psychopath in office realises his psychopathy. The redirection of aggression from the external, stereotype enemy against this process itself (not against the ruler as another stereotype, as in many of the actionist ideologies of revolution) is a rational therapeutic measure. If it is true that wars originate in the minds of men, it is equally true that they will cease when individuals decline to follow their leaders into war. Fromm[6] has already pointed to the incentive mechanism upon which this may take place, in the growth of spontaneity and security in family life. The activities of power-groups present the main barrier today to any such realisation, and a show-down between authority and psychiatry, at least as violent as that which is taking shape in penology, seems inevitable. In the course of it, we may find it necessary to question the political assumptions of our civilisation, and of the whole conception of power, far more radically than Dr. West has so far been ready to urge.

TREATMENT OF WHOOPING-COUGH

SIR,—Whooping-cough in infancy is a serious disease which becomes particularly grave when bronchopneumonia supervenes. The following case may be of interest.

A premature baby, born at the 7th month, had been reared on diluted cow's milk since the age of 3 months: at 2 months she had had bronchopneumonia.

When 7 months old she contracted whooping-cough. She was first seen after 10 days of severe coughing, frequently culminating in vomiting; weight 5·9 kg. When seen 12 days later, the baby was gravely ill, cyanosed, dyspnœic, temp. 39°C; rhonchi and crepitations (mostly crackling at the bases) all over chest. She had just had a 4-day course of sulphadimidine and penicillin without benefit.

Chloramphenicol was started with one capsule of 250 mg. 6-hourly. On the evening of the 2nd day the temperature began to fall by lysis; the next day it was normal and it remained so. The cough became infrequent and loose, and vomiting abated. Unfortunately the mother ran short of the drug after 2 days' administration (2 g. in all); but by the time the drug was resumed after a break of 2 days the baby was making steady progress. Chloramphenicol in the same dosage was continued for 3 further days; and 12 days later the chest was clear and the weight was once more 5·9 kg.

In an investigation now in progress two further cases (one in a 9-month-old baby, the other in a rachitic baby of 2 years and 9 months) of bronchopneumonia complicating whooping-cough and developing 17 and 19 days, respectively, after the onset of cough have been treated with 'Aureomycin' with equally good results; in neither case were penicillin, sulphonamides, or sedatives used.

In view of the difficulty experienced by Dr. Gray (*Lancet*, Jan. 28, p. 150) in administering the drug to young babies, I might add that the following method of preparation has been found satisfactory: aureomycin 4 g., liquid extract of liquorice 5 ml., gum acacia 10 ml., syrup q.s., and water 160 ml.

Public Health

Influenza

IN the 126 great towns of England and Wales the following pneumonia cases and deaths and influenza deaths have been recorded:

	Week ended								
	Dec. 31, 1949	*January, 1950*				*February, 1950*			
		7	*14*	*21*	*28*	*4*	*11*	*18*	*25*
Pneumonia									
Cases*	496	639	550	487	494	594	582	630	595
Deaths	310	299	300	233	305	354	378	353	304
Influenza									
Deaths*	28	52	47	39	47	61	80	76	73

* Including influenzal pneumonia.

Totals for the great towns in the first eight weeks of the last three years are as follows:

	1948	*1949*	*1950*
Pneumonia			
Cases	3748	5131	4575
Deaths	2210	2982	2526
Influenza			
Deaths	165	737	480

Notifications in England and Wales of primary and influenzal pneumonia have been as follows:

Week ended								
Dec. 31, 1919	*January, 1950*				*February, 1950*			
	7	*14*	*21*	*28*	*4*	*11*	*18*	*25*
842	1120	991	850	902	1187	1228	1189	1093
Corresponding week in 1948–49—								
1050	1184	1184	1050	935	1016	1139	1469	1607

It is learned from the Public Health Laboratory reports that virus B has been isolated from a few odd cases in widely scattered areas—e.g., Doncaster, London, Exeter, Inverness, and Ipswich.

The following cities had the largest numbers of notifications of pneumonia for the week ended Feb. 25:

London, 131, Sheffield, 58. Manchester 52, Birmingham 54. Liverpool 42. Sunderland 28.

As regards the North in particular, the following figures of pneumonia notifications in areas in which influenza has been prevalent are of interest:

	Week ended				
	Jan. 28	*Feb. 4*	*Feb. 11*	*Feb. 18*	*Feb. 25*
Durham	84	107	86	87	98
Yorks. East Riding	16	7	7	14	13
Yorks, North Riding	13	22	16	19	12
Yorks, West Riding	107	125	134	125	216

Local outbreaks of mild influenza due to virus B continue to occur and are widely distributed. There is no sign of an epidemic. There are casual reports of a high incidence of upper respiratory disease in some practices, and it seems probable that much of this is due to hæmolytic streptococci.

Notification by Hospitals

Infectious Diseases.—The Ministry of Health has directed (R.H.B. [50] 22) that on admission of cases of notifiable disease. including tuberculosis, hospitals should notify the medical officer of health of the area from which the patient has been admitted of the patient's name, age, address, and diagnosis. The medical officer of health should also be notified of any change in diagnosis, and on the patient's discharge from hospital or sanatorium. "This information is intended to facilitate the M.O.H.'s work, but it will also be useful in bringing to light previously unnotified cases." Infectious-disease hospitals have no statutory duty of notification. Nevertheless. "formal notification from hospitals should be sent to the M.O.H. of the borough or county district in which the hospital is situated, except in the County of London, where notifications should be sent to the M.O.H. of the Metropolitan borough from which the patient has been admitted"; and it is particularly important that the local medical officer of health should be notified without delay of diseases of serious epidemiological importance first diagnosed in hospital.

Aftercare.—The family doctor should have early information of the discharge of a patient from hospital and should arrange with the local health authority for services such as home nursing and domestic help.

> "There are, however, cases where direct information, including any necessary medical details, should pass from the hospital to the local health authority, in order to avoid a break in the services provided, e.g., in the provision of special nursing requisites for paraplegics, or more simply to arrange for immediate home nursing attention or domestic help. Such arrangements should, of course, only be made with the patient's agreement and the family doctor should be informed that arrangements have been made direct with the local health authority. A form agreed regionally for transmission of this information would be useful."

In maternity cases where either the local health authority's midwife and/or antenatal clinics have supervised the patient before admission to hospital, information regarding treatment and any abnormal occurrence should be supplied to the medical officer of health on the patient's discharge. "Advance information should. of course. be given whenever a maternity case is discharged early and requires care through local health authority service."

Children.—"The joint responsibility of the family doctor and the medical officer of health or school medical officer is recognised and it is suggested that the same information should be sent to the family doctor and. for a school child. to the school medical officer or, for a child under school age, to the medical officer of health of the county or county borough in which the child lives.

> "The arrangement . . . should include information on the discharge of babies born in hospital, especially premature births, necessary details of feeding in such cases, and deaths of children in hospital. If it is possible, information about premature babies should be sent before their discharge. The form signed by the parent on the child's admission to hospital should include a note intimating that, in the absence of a request to the contrary, information sent to the doctor will also be sent to the school medical officer or medical officer of health of the local health authority unless the parents object."

The arrangements for the supply of information should, the circular concludes. be extended to children who have attended as outpatients where the information would be of value.

Obituary

Prof. JOHN RYLE

FROM Cape Town, J. T. I. writes: "Guy's men the world over will be sad to hear of John Ryle's death. My own friendship with him went back over twenty years to my days as ward-clerk at Guy's. His teaching rounds were a delight, and one came away quite unaware of having stood for over two hours on hard ward-floors. No matter how foolish the suggestion one made, he listened without interruption and he pointed out the fallacies in such a kindly way that one felt one had made a contribution to the afternoon! Later I was lucky enough to win his friendship and spent many happy weekends and holidays at Glatting in Sussex, where. as we sat on the South Downs looking at the perfect view, he would discourse on all manner of subjects in his wise way. After I went into academic life and came to South Africa, we could keep in touch only by letter. It was therefore a great privilege for us all to see him again during his lecture tour here. Alas, it was already clear that he was stricken, and it is sad that he lived to enjoy so little of his retirement."

Appointments

ANDREWS, R. H., M.D. Lond., M.R.C.P.: deputy superintendent, Tehidy Sanatorium, Cornwall.

BLACK, W. R., M.B. Edin., F.R.C.S.E.: consulting surgeon, Weston-super-Mare Hospital.

CHAPMAN, MARGARET, M.B. Glasg.: asst. M.O., Renfrew County.

CRAIG, R. A., M.D. Lond., M.R.C.P.: consulting chest physician, Bristol clinical area.

LEITCH, J. A., M.B. Edin.: asst. M.O., maternity and child welfare, Nottingham.

LOVEL, K. W., B.M. Oxfd, M.R.C.P.: medical registrar, thoracic unit, Hospital for Sick Children, Great Ormond Street. London.

MILLING, P. F., M.B. Camb., F.R.C.S.: asst. surgeon. throat and ear dept., Brompton Hospital, London.

ROSTRON, K. W. B., M.B. Camb., D.O.M.S.: consulting ophthalmic surgeon, West Cornwall clinical area.

WARWICK. ELSPETH, M.B. Edin., D.P.H.: senior M.O., maternity and child welfare, Nottingham.

Births, Marriages, and Deaths

BIRTHS

ASHCROFT.—On March 4, at Newcastle upon Tyne. the wife of Dr. Anthony Ashcroft—a daughter.

BELL.—On March 4, in Edinburgh, the wife of Dr. J. D. Bell—a daughter.

FAWKES.—On March 3, at Port-of-Spain, Trinidad, the wife of Dr. M. A. Fawkes—a son.

HART.—On March 7, the wife of Dr. T. N. Hart—a son.

KAY.—On March 10, the wife of Dr. Ronald Kay—a son.

MURDOCH.—On March 4, the wife of Dr. Robin Murdoch—a son.

SHERLOCK.—On March 6, at Ipswich, the wife of Dr. A. Sherlock—a daughter.

SUCHETT-KAYE.—On Feb. 27, in London, the wife of Dr. A. I. Suchett-Kaye—a son.

MARRIAGES

HUGHES—PEEK.—On March 4, at Drewsteignton, Devon. Mark Henry Hughes, B.M., to Veronica Drewe Peek.

JONES—BARTHOLOMEW.—On Feb. 11, at Frimley, David Elgan Jones, M.B., to Elizabeth Maureen Bartholomew, S.R.N.

DEATHS

BAILEY.—On March 5, at York, Henry Bailey, M.R.C.S.

BRANSON.—On March 5, at Bury St. Edmunds, William Philip Sutcliffe Branson, C.B.E., B.A., M.D. Camb., F.R.C.P., aged 75.

BROWN.—On March 3, at Towyn, Merioneth, Eric Barlow Brown, M.B. Edin.

HOLLINS.—On March 5, at Amwell, Ware, Herts. Thomas John Hollins, B.A. R.U.I., M.D. N.U.I.

LEWIS.—On March 5, at Hove, John Stephen Herbert Lewis, M.D. Lond., aged 67.

MCKELVEY.—On March 5, at Penylan, Cardiff, Thomas McKelvey, M.B. R.U.I.

MORIARTY.—On March 5, in Birmingham, Rowland Eagar Moriarty, L.R.C.P.E., aged 75.

POOLE.—On March 10, Thomas Brice Poole, M.D. Durh., aged 80.

STEPHENS.—On March 9, at Coleshill, Harold Freize Stephens, M.R.C.S., aged 65.

STURDY.—On March 10, at Bognor Regis, Harry Carlile Sturdy, M.D. Durh.

WATSON.—On March 5, at Leigh-on-Sea, William Douglas Watson, T.D., M.R.C.S., D.P.H., aged 79.

Notes and News

EXCHANGE OF PRACTICES

BEFORE July 5, 1948, a general practitioner who for some reason, personal or domestic, wanted a change in the type of practice or area in which he worked was able to arrange an exchange with another practitioner. Thus the man with years of industrial practice behind him, who desired less arduous practice in the country or at the seaside, might exchange with a younger man who found his family commitments increasing. Since the National Health Service started, only two exchanges have been made within the service; but the Medical Practices Committee believe that normally no difficulty need arise in making the necessary arrangements. In a letter to executive councils they point out that before practitioners proceed with a proposed exchange they will require assurances (1) that one will be admitted to practise in the area of the other, and (2) that the transfer of patients from one to the other will automatically follow, subject of course to the free right of patients to choose for themselves. The committee hope that only in very exceptional cases will such assurance be withheld by the executive councils concerned (in consultation with their local medical committees). The fact that either area had been declared a "closed area" should not generally affect the decision to agree to an exchange.

The initiative must of course be taken by the doctors themselves. The normal channels would be by advertisements in the journals or through the Medical Practices Advisory Bureau at B.M.A. House, Tavistock Square, London, W.C.1. The bureau is anxious to play its part and remarks that "the greater the number of practitioners who are registered with the bureau for this purpose, the greater the opportunity of effecting suitable introductions."

THE TEACHING OF ANATOMY AT OXFORD

AN exhibition of unusual interest in the Radcliffe science library at Oxford shows the "History of the Teaching of Anatomy at Oxford, 1600–1950"; and some of the older books borrowed from the Bodleian carry the history back to still earlier centuries. The earliest known representation of dissection in England may be seen in a crude coloured illustration to an English anatomical treatise in Latin of the late thirteenth century. The story of anatomy teaching in the university is traced from its original home in the east quadrangle of the Bodleian in 1613, where a German visitor reported seeing "several skeletons, the skin of a man, a basilisk and a piece of the Pillar of Salt." Later the Ashmoleum museum became the headquarters for the teaching of this branch as well as for all branches of science in Oxford. In 1765 a new school was built at Christ Church and it was here that Dr. Kidd held office; an assortment of anatomical specimens and instruments from this building is shown. The department was moved to the university museum in 1860, and when Prof. Arthur Thomson was lecturer interested friends had a small tin shed erected to give to the subject a building unshared by others.

STANDARDISING SPOONS

RED spoons for measuring medicine are recommended by the British Standards Institution. In discussions with the Pharmaceutical Society and the Ministry of Health, the institution has been considering the question of variations in the size of teaspoons and tablespoons. Different-sized spoons for cookery and for medicine are now proposed. The American fluid ounce is larger than the Imperial fluid ounce; and to allow American and British recipes to be interchanged without confusion, it has been thought essential to specify American standards for spoons used in cookery. It is therefore suggested that spoons for medicines should be smaller than others. The new size proposed for medicine tablespoons is $^1/_{40}$, and for cookery tablespoons $^1/_{32}$, of an Imperial pint; for medicine teaspoons $^1/_{160}$, and for cookery teaspoons $^1/_{96}$, of an Imperial pint.

Tuberculosis on Television

Dr. R. R. Trail, director of Papworth Village Settlement, will introduce a group of experts who will demonstrate the diagnosis, treatment, and prevention of tuberculosis in the B.B.C. television service on March 20. The programme is being arranged by Dr. Brian Stanford and will be produced by Andrew Miller Jones.

University of Oxford

On March 7 congregation rejected by 69 votes to 35 a resolution to amend the statute of Dec. 13 which regulates salaries. The rejected amendment affirmed that there was no justification on academic grounds for paying salaries of different grades to members of comparable grades unless some had extra administrative or clinical duties. It accordingly proposed that no distinction should be made on the basis of a medical qualification between members of the departments specified in the statute.

University of Cambridge

On March 4 the following degrees were conferred:

M.D.—D. J. Conway, J. M. Ranking, A. S. Wigfield, D. G. Wraith.

M.B., B.Chir.—*F. W. Huddy, *D. H. Mackenzie, *P. M. Smythe.

* By proxy.

University of Birmingham

Prof. A. C. Frazer, who has been appointed to a guest lectureship by the United Universities of Sweden for the session 1949–50, visited Sweden from March 3 to 17 and lectured at Stockholm, Uppsala, and Lund. During April and May he is to lecture at a number of American universities.

Mr. A. J. H. Rains has been appointed lecturer in surgery from March 1. Dr. J. M. French has been made an honorary member of staff of the department of pharmacology.

University of Manchester

Dr. A. C. P. Campbell has been appointed Procter professor of pathology and pathological anatomy. Till he takes up his duties early this summer, Prof. S. L. Baker will continue to hold the chair of pathology together with the directorship of the pathological section of the centre for research in chronic rheumatism, which will then become a full-time appointment.

Professor Campbell was educated at Foyle College, Londonderry, and the University of Edinburgh where he graduated in medicine in 1930. In 1932 he became a member of the Royal College of Physicians of Edinburgh. After holding junior hospital appointments he became a clinical tutor in the Edinburgh Municipal Hospitals and Crichton research scholar of the department of [illegible] h University. In 1935 he was elected to a [illegible] ellowship and became a research fellow in [illegible] rvard University. On his return to this [illegible] was appointed an assistant in pathology at Edinburgh and in 1937 he became lecturer in neuropathology and lecturer in morbid histology and, in 1939, pathologist to the Edinburgh Royal Infirmary. In the same year he became F.R.C.P.E. During the late war he served in the R.A.F. as pathologist to the General Hospital at Ely with the rank of wing-commander. His original work has been principally in the fields of neuropathology, and the pathology of the skin and of certain lesions consequent on exposure to high altitudes.

University of Bristol

Dr. A. H. Gale has been appointed full-time director of medical postgraduate studies, and lecturer in epidemiology, in succession to Mr. A. J. M. Wright, who retires at the end of the present session. Dr. Gale is at present a medical officer of the Ministry of Health, and he was formerly a medical officer of the Ministry of Education.

Royal College of Surgeons of England

At a meeting of the council on March 9 with Sir Cecil Wakeley, the president, in the chair, Prof. Ian Aird, Mr. F. W. Holdsworth, and Mr. C. Price Thomas were admitted to the court of examiners. Honorary fellowships were awarded to Prof. P. Bailliart of Paris and Dr. Derrick Vail, professor of ophthalmology, North Western University, Chicago. Mr. R. D. Owen, F.R.C.S.E., of Cardiff was elected to the fellowship ad eundem.

Dr. James Craigie, F.R.S., and Dr. L. Foulds were appointed Imperial Cancer Fund lecturers for 1950. A diploma of membership was granted to J. W. Fullerton.

On March 20 the Queen will visit the college to receive the honorary fellowship.

Glasgow Royal Infirmary Club

This club held its first annual dinner since 1939 on March 9, when Sir Alexander Macgregor was in the chair. The guests were Dr. O. H. Mavor, Lord Boyd-Orr, F.R.S., and Mr. W. A. Sewell, and 120 members from all parts of the United Kingdom attended. The secretary is anxious to get in touch with all former residents of the Glasgow Royal Infirmary, so that the roll of the club may be complete. Any who did not receive notice of this year's dinner are asked to send their names and addresses to Mr. W. S. Mack, 20, Royal Terrace, Glasgow, C.3.

Renal Association

The first meeting of this association will be held on Thursday, March 30, at 4.30 P.M. at the Ciba Foundation, 41, Portland Place, London, W.1. After the election of officers and other business, Mr. D. F. Ellison Nash will read a paper on Form and Function in the Renal Tract.

French Honours

On the occasion of his visit to the French Hospital in London on March 9, the French President, M. Auriol, decorated Dr. James Moore, Mr. H. W. Wright, and Dr. Andrew Morland as chevaliers of the Legion of Honour.

Claims to Sickness Benefit

In England and Wales new claims to sickness benefit under the National Insurance Act during the weeks ended Feb. 7, 14, 21, and 28 were as follows: 189,700, 180,400, 177,300, and 165,000; during February, the weekly average was 178,100. The weekly averages from February, 1949, to January of this year were: 179,800, 185,200, 114,400, 97,700, 83,500, 78,600, 88,800, 100,900, 119,100, 136,200, 96,700, and 154,900.

Regional Psychiatrists

The chairmen of regional hospital boards have already been informed of the approval by the Ministry of Health of fixed salaries of £1800, £1900, or £2000 for regional psychiatrists. A further circular (R.H.B. [50] 20) points out that boards may adopt any of three arrangements:

1. The appointment of a whole-time officer who would give his whole time to administrative work as regional psychiatrist and would be remunerated at one of the rates mentioned above.

2. The appointment of a whole-time officer who would give part of his time to administrative [illegible] iatrist, for which he would be remunerated [illegible] roportion of the fixed rate mentioned abov[illegible] of his time to clinical work for which he would be remunerated according to his status as consultant or senior hospital medical officer.

3. The appointment of a part-time officer. In this case the arrangement would be as follows: (*a*) for the part-time work as regional psychiatrist on the staff of the board, the officer would be paid the appropriate proportion of the fixed salary (£1800, £1900, or £2000, as the case may be); (*b*) for clinical work the officer would have a separate contract and would be paid in accordance with section 5 of the Terms and Conditions of Service which deals with part-time appointments. Under this third arrangement, relating to part-time officers, nine is the maximum number of notional half-days in respect of which remuneration for work as regional psychiatrist and for clinical work combined can be claimed.

Difficulties in the Dental Service

Mr. A. E. Rowlett, president of the International Dental Federation and a vice-president of the British Dental Association, is reported by the *New York Times* (March 11), to have said in New York last week that Britain's National Health Service had failed disastrously to better the dental health of a large number of people, especially children of school age. "The plight of British dentistry today is deplorable because the Labour Government insisted on setting up a comprehensive scheme to care for every man, woman, and child in the country, without first experimenting on a small scale"; and "everyone now agrees that it was a disaster for us not to ensure school children their fair share of treatment." The great majority of patients were "terminal" cases—elderly people who required dentures or other intricate work. Whereas dentists catering for such people had been well paid, school dentists had been "miserably underpaid"; and there had been a mass exodus of dentists from the service of youthful patients to the fitting of dentures for elderly persons. The priority given to terminal cases threatened to undermine Britain's dental health. Furthermore, British dental standards were deteriorating because dentists were discovering that they must receive prior approval before they might undertake any but minor treatment. Mr. Rowlett estimated that since the service started demands for dental treatment had increased by more than 300%. Comprehensive dental training had suffered heavily. When the most inexperienced dentist could make a fairly large income by doing only the simplest work, there was little incentive for research or apprenticeship with dentists of high standing.

The Lancashire education committee, according to the *Times* (Feb. 21), has decided to pay a bonus of £200 a year to all school dentists, in an attempt to keep them from resigning to take up more lucrative private practice. The committee was told that, without early action, the remaining school dentists would be lost. Already thirteen clinics had been closed, and 40,000 school-children were without dental supervision.

Course on Rheumatic Diseases

As already announced, a weekend course on the chronic rheumatic diseases will be held at the rheumatism unit of St. Stephen's Hospital, Fulham Road, London, S.W.10, on March 25 and 26.

Institute of Almoners

The annual general meeting of the institute will be held on Saturday, March 25, at 2.30 P.M., at the Town Hall, Leamington Spa. Dr. Thomas McKeown, professor of social medicine in the University of Birmingham, will give an address.

North of England Ophthalmological Society

Dr. Ramón Castroviejo, of New York, is to deliver two lectures to this society. On Thursday, March 30, at 3.30 P.M., at the Royal Infirmary, Manchester, he is to speak on Cataract Surgery, and on Friday, March 31, at 3 P.M., at the Leeds Medical School on Keratoplasties and Keratectomies. Further particulars will be found in our advertisement columns.

International Hæmophilia Society

The annual general meeting of this society will be held on Sunday, March 26, at 2.30 P.M. at the Society for Visiting Scientists, 5, Old Burlington Street, Piccadilly, London, W.1. Anyone who wishes to attend should send a stamped addressed envelope to the secretary of the society at the Galton Laboratory, University College, W.C.1.

Medical Society of London

Proposing the toast of The Medical Society of London, at its 170th anniversary dinner on March 9, Mr. Laurence Irving commented on the kindly faces of the general practitioners, the wise and benevolent faces of the physicians, and the eager faces of the surgeons, by which he was surrounded. He had relied in life on the friendship of practitioners and a bathroom cupboard full of proprietary preparations. (How immutable these were! The one he used for cholera bore the testimony "without it I should never have got through the Second Matabele War.") His mother, having abandoned playing the part of *Trilby* for pioneer work in infant welfare, had later taken up astrology and foretold disaster if ever he should get wet feet. During the first world war he had joined the Royal Air Force, "and so passed safely over the dangers which threatened me"; but in the second war he was too old to fly, got his feet wet, was evacuated to hospital with what felt like a fox gnawing at his vitals, and (just when a comfortable bed and much kind attention were what he and his fox most needed) was interviewed by a man with piercing eyes who said "Are you happy in your married life?" This surprised him, and he feared that "my unwitting falsehood has gone echoing down the corridor of scientific medicine." After which brief autobiography Mr. Irving was good enough to say that artists and doctors had their similarity; but the artist was preoccupied with self-expression and the doctor with self-denial. Doctors were like lifeboatmen, constantly at the call of shipwrecked humanity. Mr. Lionel Norbury, responding as president, spoke with approval of the recent innovation of bringing young non-members to the society's meetings to describe new work. The Lettsomian lectures had been given, very notably, by Mr. Dickson Wright, and Sir Henry Souttar would give the oration in May. The society's quarters at 11, Chandos Street had been renovated, thanks largely to Dr. Hope Gosse. Dr. Cuthbert Dukes, proposing The Guests, said that they had at least one desirable quality in common: they were all males. But he abandoned his original intention of classifying them into those born great and those whose greatness had been thrust upon them—the congenital and the acquired. The presence of Sir Gordon Gordon-Taylor (shortly off to lecture again around the Mediterranean) reminded Dr. Dukes of the cadet's answer on the function of the cavalry in modern war: "The cavalry give an air of distinction to what would otherwise be a vulgar brawl." But he seemed to see less advantage in medical journalism, and went so far as to quote an old statement that "disease as it stalks through the land cannot keep pace with the incredible vice of writing about it." Responding in his rôle of president of the Royal College of Surgeons, Sir Cecil Wakeley ignored this aspersion; but he could not conceal his inside knowledge that the Medical Society of London had always been "an interesting, jolly, friendly society."

Auxiliary Royal Army Medical Corps Funds (1939)

The annual general meeting of the fund will be held at 11, Chandos Street, London, W.1, on Monday, April 3, at 5 P.M.

Rugby School Appointment

Dr. J. P. Sparks, senior medical registrar at the Postgraduate Medical School of London, has been appointed medical officer to the school in succession to Dr. R. E. Smith. Dr. Smith has been appointed consultant physician to the Coventry, Nuneaton, and Rugby Group of Hospitals, but he will continue to act as consulting physician to the school.

B.M.A. Pamphlet on Medical Ethics

The British Medical Association originally prepared their booklet *Ethics and Members of the Medical Profession* for the information of doctors who had lately qualified, many of whom were setting up in independent practice. The council of the association are now arranging to send a copy to all doctors, members and non-members of the association alike, so that they may have an opportunity of seeing the guidance which is being offered to their younger colleagues.

Albania Withdraws from W.H.O.

The Albanian deputy minister for foreign affairs has announced his country's withdrawal from the World Health Organisation in a letter which asserts that the organisation has discriminated against Albania. So far 68 countries have ratified the W.H.O. constitution; and 5 other countries have withdrawn—Rumania this year (see *Lancet*, March 4, p. 427) and previously the U.S.S.R., the Byelorussian S.S.R., the Ukrainian S.S.R., and Bulgaria.

Anti-histamines as "Cold Cures"

The U.S. Food and Drug Administration is ready, says a B.U.P. report, to take court action if necessary against manufacturers of some anti-histamine drugs sold as "cold cures." However, Dr. Paul Dunbar, director of the administration, believes that, to sustain a court case, the administration would have to prove that the drugs had caused injury often enough to show that such injury was not suffered only by extremely sensitive people. So far the administration has seen nothing to warrant either action for misbranding or a complete reconsideration of the earlier decision permitting sales without prescriptions. "We are watching every medical report," added Dr. Dunbar. "When we find any scientific evidence that we were wrong, we shall not hesitate to act."

Library Association

The medical section of the Library Association held its first annual meeting in London on March 10, under the chairmanship of Mr. W. R. Le Fanu. This section was previously a subsection of the universities and research section. The chairman said that a letter from the Surgeon-General of the U.S. Army explained in detail the reasons for abandoning the *Index-Catalogue*; and he described the services which are to be provided instead—an improved *Current List*, a special supplement to the *Library of Congress Catalog of Printed Cards*, and volumes covering the historical monographs in the Army medical library.

Mr. Le Fanu is giving a lecture, for those interested in medical librarianship, at the association's headquarters, Chaucer House, Malet Street, London, W.C.1, on Friday, March 17. It is hoped that this will be the first of a series.

Future of Peckham Health Centre

As we announced last week, the centre has had to close through lack of funds. At a meeting of the London County Council on March 8 it was stated that some time ago there had been discussions between the chairman of the L.C.C. health committee and the authorities of the centre as to how the centre and the council could cooperate. Under the National Health Service the council is responsible for providing various free services which it was thought might find a place in the centre. But at that time the centre authorities were unable to accept the proposals made by the council as they involved changes in the rules of the centre. A new scheme is now being considered, but as the Ministry of Health, the Executive Council for London and the London Medical Committee for general practitioners' services, and the health and education committees of the L.C.C. will have to be consulted it may be some time before a final decision is reached.

Acquittal on "Mercy-killing" Charge

At Manchester, New Hampshire, last week, Dr. Hermann N. Sander was acquitted of a murder charge arising from his admission that he had introduced air into the circulation of a 59-year-old woman who was dying of cancer. At the trial it was argued for the defence that the air had not entered a vein and that at the time of the attempted injection the patient was already dead.

Sickness and Unemployment Benefits

Under the National Insurance (Claims and Payments) Amendment Regulations, 1950 (S.I. 297), the time in which a sick or unemployed person can claim increases of benefit for his dependants is extended to one month. The regulations came into force on March 13. The times for claiming the main benefits remain unchanged. A claim for personal unemployment benefit must be made on the day for which benefit is claimed. For personal sickness benefit, incapacity must be notified within three days from the first day of incapacity and benefit must be claimed not later than ten days after the first day of incapacity.

South-West Metropolitan Regional Association of Psychiatrists

At a meeting of this association on Feb. 22, the following officers were appointed: chairman, Dr. A. Spencer Paterson; hon. treasurer, Dr. H. S. Klein; and hon. secretary Dr. D. Shaw (Belmont Hospital, Brighton Road, Sutton, Surrey). Eleven members were appointed to the council; the seven vacancies on the council will be filled by postal ballot.

Doctors and their friends are invited to see the Boat Race (April 1) from the Hammersmith wharf of Messrs. Vitamins Ltd. Early application should be made to them (dept. *B.R.2*) at Upper Mall, London, W.6.

Diary of the Week

MARCH 19 TO 25

Monday, 20th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5.30 P.M. Prof. Charles A. Wells: Varieties and Modes of Renal Failure.

HUNTERIAN SOCIETY
7.30 P.M. (Talbot Restaurant, 64, London Wall, E.C.2.) Dr. Geoffrey Marshall, Mr. T. Holmes Sellors: Modern Trends in the Diagnosis and Treatment of Pulmonary Tuberculosis.

Tuesday, 21st

ROYAL COLLEGE OF OBSTETRICIANS, 58, Queen Anne Street, W.1
5 P.M. Prof. Arthur T. Hertig (Boston): Hydatidiform Mole and Chorionepithelioma. (Fairbairn lecture.)

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. G. B. Dowling: Cutaneous Tuberculosis.

BRITISH MEDICAL STUDENTS ASSOCIATION
5.30 P.M. (London Hospital Medical College, E.1.) Dr. Marjory Warren: Geriatrics.

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mrs. Barbara Bosanquet: The Quality of the Rural Population.

Wednesday, 22nd

HARVEIAN SOCIETY
8.45 P.M. (26, Portland Place, W.1.) Sir Henry Cohen: Harvey and the Scientific Method. (Harveian lecture.)

UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. T. D. M. Roberts: Primary Visual Receptors.

Thursday, 23rd

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Sir Paul Mallinson: Psychiatry lecture-demonstration.

MEDICO-LEGAL SOCIETY
8.15 P.M. (26, Portland Place, W.1.) Dr. J. A. Gorsky: Alcohol and the Motorist.

Friday, 24th

ROYAL COLLEGE OF [illegible]
5 P.M. Dr. V. E. [illegible] Oral Cavity.

MAIDA VALE HOSPI[illegible] W.9
5 P.M. Dr. S. Nevin: Neurological demonstration.

BIOCHEMICAL SOCIETY
11.30 A.M. (University College, W.C.1.) Short papers and demonstrations.

Saturday, 25th

ST. STEPHEN'S HOSPITAL, Fulham Road, S.W.10
10 A.M. (Rheumatism Unit.) Prof. G. W. Pickering: Significance of the Effect of Compound E in Rheumatoid Arthritis. (Opening address of weekend course on the Rheumatic Diseases.)

VAGOTOMY AND PARTIAL PYLORECTOMY

A NEW PROCEDURE FOR DUODENAL ULCER

A. DAVIS BEATTIE
M.B. Lond., F.R.C.S.
SURGEON, LEICESTER GENERAL HOSPITAL

DUODENAL ulceration is becoming an increasing economic problem. Not only does the rising stress of modern life, in certain occupational classes of the population, lead to an increasing incidence of peptic ulcer in these groups but also it is responsible for a similar failure-rate from medical treatment. Partial gastrectomy, which for nearly twenty years has been the recognised surgical answer to this problem, is not the entire success originally anticipated. The initial Polya technique has gradually had to be modified to eliminate, so far as possible, the problem of recurrent ulceration. This has necessitated an increasingly drastic resection of the gastric mucosa, the culmination of which is seen in the various types of subtotal gastrectomy now in vogue. Such radical procedures certainly effect a cure of the ulcer diathesis by reducing the gastric acidity, but they are both unæsthetic and needlessly drastic operations for duodenal ulcer, particularly when the ulcer has sometimes to be left in situ.

RESULTS OF GASTRECTOMY

The relatively small stomach which results from the radical resections of modern gastrectomy is often incapable of carrying out its physiological functions adequately. It can neither hold a sufficiency of food nor digest it properly; and not surprisingly this leaves much to be desired from both physiological and economic standpoints. Recent analyses of the after-results of this type of operation confirm the original view of St. John et al. (1939) that they are not nearly so satisfactory as was originally believed. Gastrectomy is a mutilating procedure, and a high proportion of patients suffer afterwards from recurrent gastro-intestinal upsets, which are often sufficiently severe to affect adversely their whole economic life. The symptomatic and economic results in over 1000 cases of gastrectomy, reviewed by six different workers, were as follows:

	Gastro-intestinal symptoms	*Easy fatigue*	*Poor economic results*
Gastric ulcer:			
Warren and Meadows (1949)	58·8%	52 9%	35·2%
Watson (1947)	62·7%	..	16·9%
Duodenal ulcer:			
Jordan (1941)	60 0%	..	..
Watson (1947)	58·9%	..	13·2%
Warren and Meadows (1949)	40·5%	32·4%	8·1%
Allen and Welch (1946) ..	34·0%	..	..
Peptic ulcer (unspecified):			
Kemp (1947)	45 0%	..	17·0%
St. John et al. (1948) ..	31·2%	..	9·4%

It will be seen that about a *sixth of the* apparently successful surgical cures are poor economic results, and that half of them are relative physiological failures.

Though this may be a comparatively small price to pay for freedom from dangerous complications or possible malignant change in the case of medically resistant gastric lesions, it ought not to be necessary in chronic duodenal ulceration which is not subject in the same degree to such hazards.

ADVANTAGES OF VAGOTOMY

A great volume of detailed research during the past ten years has proved conclusively that it is possible, by the less drastic and simpler procedure of vagotomy, to achieve an equally effective and permanent reduction of the hyperacidity which is the cause of duodenal ulceration. This operation, first successfully performed by Dragstedt and Owens (1943) in America, provides the logical and more satisfactory physiological alternative to subtotal gastric resection. Division of the vagus nerves leads not only to a great diminution in the dangerous fasting secretion and in the high acid values of the early neurogenic stage of gastric secretion but also provides considerable reduction in the acidity during the second phase of digestion (Beattie 1948). Moreover, the relief of local muscle spasm which follows it is an important contributory factor towards ulcer healing. Vagotomy is not a mutilating procedure and does not interfere radically with gastro-intestinal physiology. It is a much more rapid procedure than gastrectomy, thus producing less operative shock; and this is reflected both in its relatively lower mortality and in its safer extension to patients in the older age-groups.

The first clinically successful vagotomies were done through a transthoracic approach, but increasing experience has shown the abdominal approach to be much more satisfactory. It is indeed doubtful whether the transthoracic operation is ever justified, since it does not permit either inspection of the lesion or assessment of its clinical pathology. There is always the possibility, in the absence of inspection of the abdomen, of an occasional disaster resulting from failure in diagnosis. Abdominal exposure and section of the vagus nerves, by a modification of the technique originally described by Dragstedt et al. (1947), is an easy and rapid procedure. It takes rather less than twenty minutes in an average case, and enables complete neurectomy to be more consistently attained than is possible through the transthoracic approach. It is only beneath the diaphragm that the plexiform vagal branches are invariably grouped together into well-defined main trunks.

RESULTS OF SIMPLE VAGOTOMY

Though more than 3000 successful vagotomies have been reported in the world literature during the last eight years, recurrent ulceration has only been demonstrated at subsequent laparotomy in three cases of duodenal ulcer in which the postoperative insulin test-meal has shown complete nerve section. Recurrent ulcer symptoms are, however, relatively common after simple vagotomy and are always due to the secondary pylorospasm which follows—the result of overaction of the sympathetic system at the pylorus after abolition of its vagal supply. This is not surprising when it is appreciated that most of the symptoms of duodenal ulcer are due to the associated pylorospasm and not to the ulcer lesion. Peptic-ulcer pain of remittent type, unlike the continuous deep pain resulting from secondary involvement of adjacent structures, is always due to muscle tension. In duodenal or pyloric lesions it results from reflex pylorospasm following irritation of the ulcer by acid gastric contents and thus occurs during the later stages of gastric digestion, when enough time has elapsed for the build-up of the requisite degree of acidity. The length of time which this requires will obviously depend both on the acidity of the gastric secretion and on the rapidity with which the stomach empties; and this fact explains the varying time-interval experienced clinically in these cases. Similarly, the typical nocturnal pain is due to a gradually increasing hyperacidity from the abnormally high night-secretion present in these patients. Reduction of the gastric acidity by alkalis, food, or vomiting allows relaxation of the associated pylorospasm, with consequent relief of symptoms; and similar results are obtained by the exhibition of antispasmodics such as belladonna. Vagotomy produces the same effect by the *immediate* reduction in gastroduodenal tone which follows it; and it is only some months after operation, when this muscle tone has returned more nearly to normal, that the clinical effects of pyloric imbalance begin to become evident.

Auxiliary Royal Army Medical Corps Funds (1939)

The annual general meeting of the fund will be held at 11, Chandos Street, London, W.1, on Monday, April 3, at 5 P.M.

Rugby School Appointment

Dr. J. P. Sparks, senior medical registrar at the Post-graduate Medical School of London, has been appointed medical officer to the school in succession to Dr. R. E. Smith. Dr. Smith has been appointed consultant physician to the Coventry, Nuneaton, and Rugby Group of Hospitals, but he will continue to act as consulting physician to the school.

B.M.A. Pamphlet on Medical Ethics

The British Medical Association originally prepared their booklet *Ethics and Members of the Medical Profession* for the information of doctors who had lately qualified, many of whom were setting up in independent practice. The council of the association are now arranging to send a copy to all doctors, members and non-members of the association alike, so that they may have an opportunity of seeing the guidance which is being offered to their younger colleagues.

Albania Withdraws from W.H.O.

The Albanian deputy minister for foreign affairs has announced his country's withdrawal from the World Health Organisation in a letter which asserts that the organisation has discriminated against Albania. So far 68 countries have ratified the W.H.O. constitution; and 5 other countries have withdrawn—Rumania this year (see *Lancet*, March 4, p. 427) and previously the U.S.S.R., the Byelorussian S.S.R., the Ukrainian S.S.R., and Bulgaria.

Anti-histamines as "Cold Cures"

The U.S. Food and Drug Administration is ready, says a B.U.P. report, to take court action if necessary against manufacturers of some anti-histamine drugs sold as "cold cures." However, Dr. Paul Dunbar, director of the administration, believes that, to sustain a court case, the administration would have to prove that the drugs had caused injury often enough to show that such injury was not suffered only by extremely sensitive people. So far the administration has seen nothing to warrant either action for misbranding or a complete reconsideration of the earlier decision permitting sales without prescriptions. "We are watching every medical report," added Dr. Dunbar. "When we find any scientific evidence that we were wrong, we shall not hesitate to act."

Library Association

The medical section of the Library Association held its first annual meeting in London on March 10, under the chairmanship of Mr. W. R. Le Fanu. This section was previously a subsection of the universities and research section. The chairman said that a letter from the Surgeon-General of the U.S. Army explained in detail the reasons for abandoning the *Index-Catalogue*; and he described the services which are to be provided instead—an improved *Current List*, a special supplement to the *Library of Congress Catalog of Printed Cards*, and volumes covering the historical monographs in the Army medical library.

Mr. Le Fanu is giving a lecture, for those interested in medical librarianship, at the association's headquarters, Chaucer House, Malet Street, London, W.C.1, on Friday, March 17. It is hoped that this will be the first of a series.

Future of Peckham Health Centre

As we announced last week, the centre has had to close through lack of funds. At a meeting of the London County Council on March 8 it was stated that some time ago there had been discussions between the chairman of the L.C.C. health committee and the authorities of the centre as to how the centre and the council could cooperate. Under the National Health Service the council is responsible for providing various free services which it was thought might find a place in the centre. But at that time the centre authorities were unable to accept the proposals made by the council as they involved changes in the rules of the centre. A new scheme is now being considered, but as the Ministry of Health, the Executive Council for London and the London Medical Committee for general practitioners' services, and the health and education committees of the L.C.C. will have to be consulted it may be some time before a final decision is reached.

Acquittal on "Mercy-killing" Charge

At Manchester, New Hampshire, last week, Dr. Hermann N. Sander was acquitted of a murder charge arising from his admission that he had introduced air into the circulation of a 59-year-old woman who was dying of cancer. At the trial it was argued for the defence that the air had not entered a vein and that at the time of the attempted injection the patient was already dead.

Sickness and Unemployment Benefits

Under the National Insurance (Claims and Payments) Amendment Regulations, 1950 (S.I. 297), the time in which a sick or unemployed person can claim increases of benefit for his dependants is extended to one month. The regulations came into force on March 13. The times for claiming the main benefits remain unchanged. A claim for personal unemployment benefit must be made on the day for which benefit is claimed. For personal sickness benefit, incapacity must be notified within three days from the first day of incapacity and benefit must be claimed not later than ten days after the first day of incapacity.

South-West Metropolitan Regional Association of Psychiatrists

At a meeting of this association on Feb. 22, the following officers were appointed: chairman, Dr. A. Spencer Paterson; hon. treasurer, Dr. H. S. Klein; and hon. secretary Dr. D. Shaw (Belmont Hospital, Brighton Road, Sutton, Surrey). Eleven members were appointed to the council; the seven vacancies on the council will be filled by postal ballot.

Doctors and their friends are invited to see the Boat Race (April 1) from the Hammersmith wharf of Messrs. Vitamins Ltd. Early application should be made to them (dept. B.R.2) at Upper Mall, London, W.6.

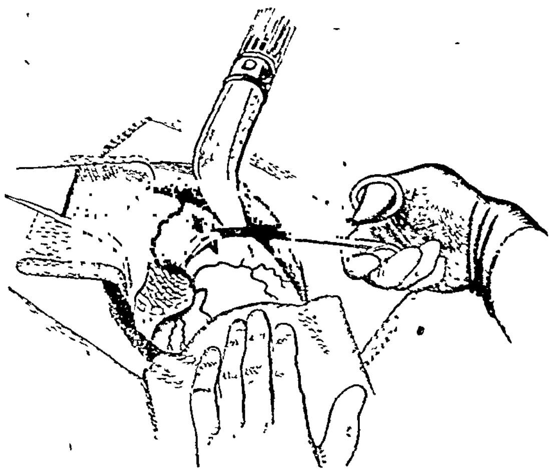

Fig. 3—Division of parietal peritoneum over lower œsophagus.

and practised by Orr and Johnson (1949). The former operation is a difficult technical feat in the presence of gross duodenal deformity, and the latter operation has several disadvantages. Besides involving the additional operation risks attendant on gastrectomy, it also leads to the removal of most of the mucosa responsible for the hormonal phase of gastric secretion. This must produce a considerable reduction in the digestive powers of the stomach—the avoidance of which constitutes one of the major advantages of vagotomy and, indeed, was the main reason for its development. An associated partial gastrectomy is therefore an unnecessarily mutilating operation from both anatomical and physiological viewpoints.

The relative failure of gastro-enterostomy combined with vagotomy to achieve perfect results in some of my cases led me to investigate the possibility of carrying out some alternative procedure at the pylorus. The first attempts along these lines were in the nature of a pyloroplasty, but it soon became apparent that this operation was not uniformly successful in providing complete relief and that it was not always feasible. It is an almost impossible technical undertaking in the presence of gross deformity of the parapyloric area, and accordingly had to be abandoned in about half the cases in favour of an associated gastro-enterostomy. The true solution to the problem was found to lie in a combined partial pylorectomy and pyloroplasty, the anterior half of the pyloric ring being excised. This operation is not only relatively easy, even in the presence of gross duodenal scarring and distortion, but also has the advantage that it often enables anterior ulcers to be excised at the same time. Moreover, it is a simple and rapid manœuvre, the whole procedure of vagotomy and pylorectomy taking little over half an hour.

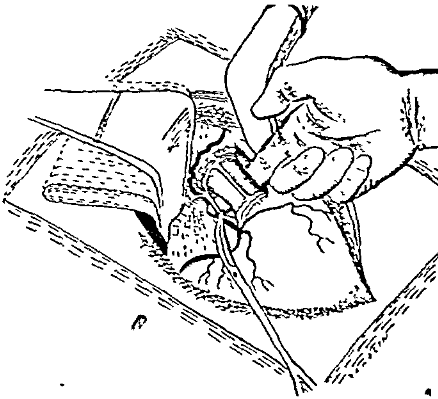

Fig. 4—Isolation of right vagus nerve.

OPERATIVE TECHNIQUE

The first essential to ease in operating lies in correct positioning of the patient on the table; fig. 1 shows the position adopted, which is a reverse Trendelenburg tilt of about 15°. The second necessity is adequate lighting, which is obtained by inclining the main lamp to about 45° and using a 'Coldlite' retractor. An upper midline incision is made, thus obtaining the necessary high exposure and avoiding the falciform ligament.

After the peritoneum has been opened, the coldlite retractor is used to lift the left hypochondriac area while the liver is mobilised by division of the left suspensory ligament (fig. 2). It is important to avoid injury to the subphrenic vessels during this manœuvre, or troublesome bleeding will ensue. The left lobe of the liver is then rotated downwards and held out of the way under an abdominal pack on the right side of the wound with a broad reflecting retractor held by a second assistant. The parietal peritoneum over the lower œsophagus is divided transversely (fig. 3) between the uppermost branches of the left gastric vessels and the point where it covers the œsophageal opening in the diaphragm. Dissection with a gauze swab on a holder will then readily expose the whole anterior surface of the abdominal œsophagus.

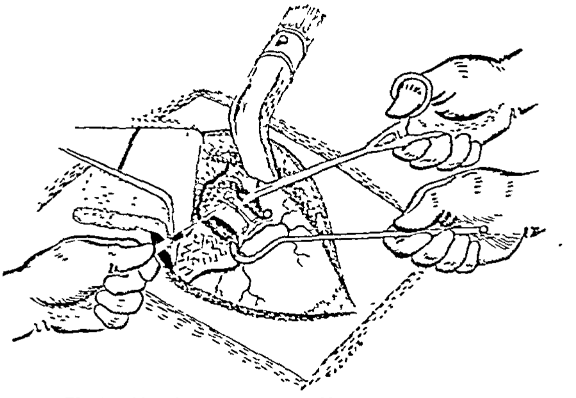

Fig. 5—Clearing œsophagus of branches of vagus.

It is now easy to insinuate the right forefinger into the lower mediastinum and to mobilise the thoracic œsophagus within it; 2 or 3 in. of this can be pulled down into the abdomen and the right vagus nerve readily identified by digital dissection in the space between the œsophagus and the right crus of the diaphragm, where it lies buried posteriorly in loose areolar tissue. It is seized with long curved forceps (fig. 4), and a lead hook is then passed round the lower œsophagus to facilitate manipulation of the latter during the subsequent steps of the operation. About 1¼ in. of the nerve is excised between forceps, and both ends are tied with silk.

Traction on the œsophagus causes the anterior vagus to stand out clearly, and it is dealt with in a similar manner, care being taken to divide all the numerous tiny branches to the œsophagus and cardia (fig. 5). Finally the œsophagus and its entire surroundings are carefully explored with the finger to ensure that no nerve branches have been missed. These stand out like taut strings in the loose connective tissue and are readily recognised. After complete hæmostasis has been obtained, the gap in the mediastinum is closed by suturing the peritoneum in front of the œsophagus (fig. 6); and the left lobe of the liver is then returned to its normal position, after it has been carefully inspected for any bleeding points which may not have been successfully controlled by pressure from the pack during the preceding stage of the operation.

The duodenum is next freed from adhesions and mobilised sufficiently for the ensuing pylorectomy.

ANALYSIS OF RESULTS OF SIMPLE VAGOTOMY

No. of years since operation	No. of cases	No symptoms	Mild symptoms	Subsequent pylorectomy	Subsequent gastro-enterostomy	Subsequent gastrectomy	Total no. of cases requiring secondary operation
1–2 ..	35	3	5	8	13	3	24
2–3 ..	59	8	24	23	1	3	27
3–4 ..	9	2	4	2	1	..	3
Total	103	13	33	33	15	6	54

The symptoms of heartburn and waterbrash are similar evidence of hyperacid gastric contents which cannot escape through the spastic pylorus; and flatulent distension is largely the direct result of ærophagy—an attempt by the patient to relieve the sensation of muscle tension resulting from the pylorospasm, which he feels subjectively as gastric distension. In fact, the only direct symptoms in duodenal ulcer which are not due to pylorospasm are those resulting from such complications as penetration into neighbouring structures, hæmorrhage, or perforation.

It is therefore not uncommon for patients to experience what seems to be a recurrence of ulcer pain some months after successful vagotomy, though flatulent distension and regurgitant vomiting are more common symptoms. They are often followed by offensive diarrhœa, as the fermenting gastric contents are finally released through the spastic pylorus to irritate the lower reaches of the gastro-intestinal tract. The distribution of such symptoms in my cases was as follows:

Occasional mild diarrhœa	35·9 %
Attacks of severe diarrhœa	14·5 %
Incapacitating diarrhœa	3·9 %
Total cases exhibiting diarrhœa ..	54·3 %
Occasional mild flatulence and eructation ..	17·4 %
Attacks of severe flatulence and vomiting ..	46·6 %
Repeated and prostrating vomiting	12·6 %
Total cases of gastric retention ..	76·6 %

Even symptoms mimicking closely those of perforation or minor gastric hæmorrhage may occur, but these too are due to acute gastric distension consequent on the pylorospasm. It is the knowledge of the occurrence of such sequelæ, and a lack of appreciation of the factors responsible for them, which have led so many surgeons to abandon vagotomy, and others to delay its adoption. My own experience regarding the unhappy consequences of simple vagotomy is shown in the accompanying table. I have had so far to reoperate on no less than 54 of my 103 cases of simple vagotomy to relieve their retention symptoms. A further 14 patients show progressive deterioration and will probably come to secondary operation in time, hence the final failure-rate is likely to approach 70%. Yet in every instance laparotomy has shown healing of the original duodenal lesion, and the only pathological finding has been the typical hypertrophy and dilatation of the stomach which follow protracted pylorospasm.

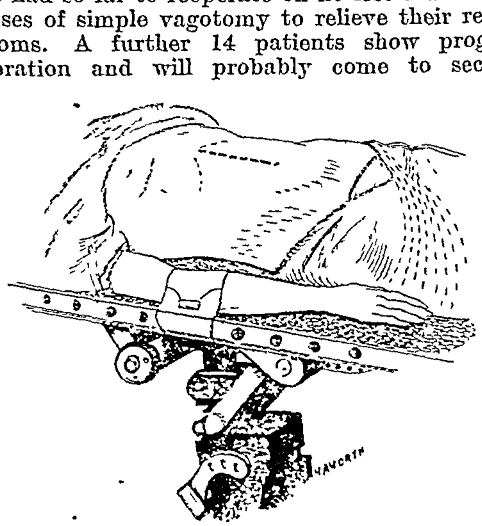

Fig. 1—Position of patient for vagotomy and partial pylorectomy.

DEVELOPMENT OF PARTIAL PYLORECTOMY

It therefore became evident to me more than two years ago, after carrying out over 100 simple vagotomies, that some associated procedure to prevent the subsequent development of pylorospasm was essential if the true value of the operation was to be obtained. There are obviously two possible approaches to this problem. Relief of the spasm could be obtained if it were possible to carry out an associated sympathectomy of the pyloric area. I attempted this in several instances without success, which is not surprising in view of the fact that the complexity of the sympathetic nerve supply to this region makes any attempt at complete denervation practically impossible. The alternative approach is by means of some mechanical procedure to eliminate the functional block at the pylorus. Gastro-enterostomy has recently been largely used for this purpose, particularly in America, but it is not without its disadvantages. Unless it is carried out at the pyloric antrum, which is a difficult technical proceeding, the distal portion of the stomach beyond the stoma can still sometimes give rise to unpleasant postoperative symptoms. Vigorous peristalsis of this segment, working against the highly spastic pylorus, can produce considerable postprandial discomfort and even typical ulcer pain.

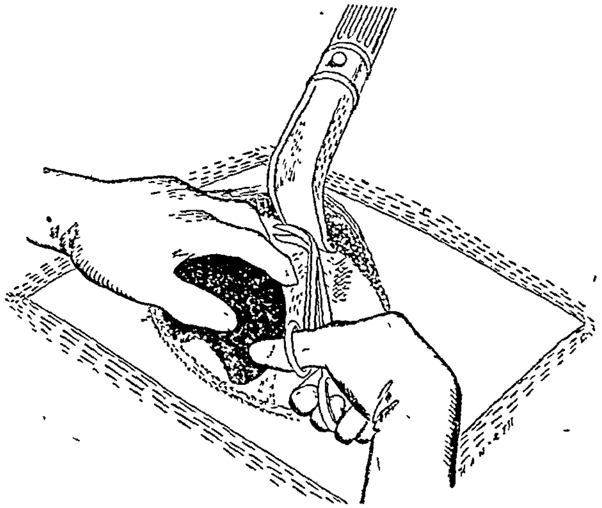

Fig. 2—Mobilisation of liver.

Moreover, the effect of an associated gastro-enterostomy is to prevent true assessment of the results of the vagotomy, besides running possible risks of subsequent jejunal ulceration in some cases. Though vagotomy has been used successfully on many occasions to cure anastomotic and jejunal ulceration following ill-advised gastro-enterostomy or inadequate gastrectomy, cases have recently been reported in which these complications have followed vagotomy with an associated gastrojejunostomy. It seems likely that, even when their neurogenic secretion has been eliminated by complete vagal section, some people may still produce a sufficiently high concentration of acid during the hormonal stage of gastric digestion to damage the susceptible jejunal mucosa.

Other possible procedures which could be undertaken as an adjunct to vagotomy, to prevent later pylorospasm, include pylorectomy with subsequent gastroduodenostomy along the lines of a Bilroth I operation; and an associated partial gastrectomy, such as that advocated

Of these 260 vagotomies 210 were done for duodenal ulcer; and of these 210 patients, 206 have been followed up for three months or more and 4 have not been traced. In addition to the 131 cases listed above of vagotomy associated with either pyloroplasty or pylorectomy there were 33 cases in which such an operation was done later to relieve gastric retention, making a total of 164 cases of vagotomy associated with either pyloroplasty or pylorectomy.

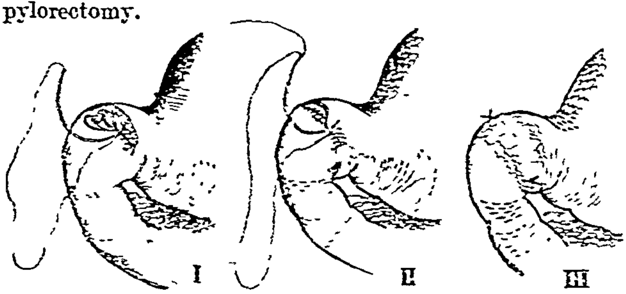

Fig. 9—Closure of duodenum.

There have been only two deaths in the total series of 210 operations. Both occurred within six days of operation and were due to leakage from the suture line. At that time I was using two suture lines of chromic catgut for the anastomosis, and neither case showed at necropsy any vestige of surviving suture material. These catastrophes were probably due to faulty catgut, but since then I have used silk for the outer layer of the anastomosis and added the covering omental "waistcoat" as an extra precautionary measure.

One other patient developed a small duodenal fistula on the fourteenth postoperative day, which closed spontaneously within a week. Apart from this there have been no postoperative complications, and the subsequent progress of all the patients has been extraordinarily satisfactory. Retention symptoms have been completely eliminated, and radiological investigation confirms the absence of pylorospasm and consequent gastric retention. Dr. Forbes Lawson (personal communication) summing up his experience from this point of view, reports:

> "In the early days, when the operation was simple vagotomy, the radiologist was more often than not defeated in his attempt to examine the duodenal cap by the very marked degree of pyloric resistance encountered. Large six-hour, and even twenty-four hour, barium residues were found in the stomach in nearly every case. Now that pyloric relief has been obtained by surgical means the picture has completely changed. The duodenal cap fills with ease, and gastric delay has disappeared, though an occasional six-hour barium residue is encountered in early postoperative cases."

There has been complete relief of ulcer symptoms in every case, and the improvement in the psychological attitude of the patients is quite outstanding. This is understandable, since they are restored to completely normal digestive life and can eat, drink, and smoke with absolute impunity. As a result there is much better adjustment to both general environment and work conditions than is possible after gastrectomy, where the "stomach consciousness" of the patient is often kept alive by the continued necessity for a modified gastric régime. A further cause of the new harmony with their surroundings experienced by these post-vagotomy patients may lie in their subsequent immunity from the reflex digestive instability which accompanies mental stress even in normal people. Many patients, at the postoperative review, volunteer the statement that their work is less effort than before and that their powers of concentration have been considerably improved. Almost all of them gain weight fairly rapidly after operation; and most of them are back at their previous trained occupations within six weeks, often despite protracted absence from it during years of previous incapacitation. Complete economic recovery and social readjustment have been obtained in every case in which the ulcer diathesis was the sole cause of the previous disability.

The only symptoms which ever arise after combined vagotomy and pylorectomy are occasional mild flatulence and intermittent attacks of transient hypoglycæmia. An admission of any digestive disturbance at all is only obtained after very close questioning, and it seems probable that the minor intermittent flatulence from which a small percentage of patients suffer does not exceed the occasional indigestion of the normal person after dietary indiscretions. Transient hypoglycæmia, on the other hand, occurs in about 10% of cases. The postoperative sequelæ not due to gastric retention were as follows:

Cases with temporary dysphagia	138 (*53·1%*)
Cases with transient hypoglycæmia:	
Following simple vagotomy	17 (*16·5%*)
Following vagotomy and gastroenterostomy ..	3 (*11·5%*)
Following vagotomy and pylorectomy or pyloroplasty	16 (*12·2%*)
Total ..	46 (*10%*)
Average gain in weight of last 135 patients during *the first three months after operation*	*9 lb.*

It is significant that the frequency of onset of transient hypoglycæmia is much the same in the gastric retention following simple vagotomy and in the much more rapidly emptying stomach after pylorectomy or gastro-enterostomy. *It cannot therefore depend on the rate of* stomach emptying, though the attacks are typical clinically of the "dumping syndrome" which may follow gastrectomy. My personal view on this subject is that, whether following gastrectomy or vagotomy, these attacks are the result of interference with the vagal supply to the liver or the pancreas, giving rise to intermittent alteration in sugar metabolism. They come on at gradually lengthening intervals and last only a few minutes; they are controlled almost immediately by oral glucose and have never yet persisted for more than eighteen months after vagotomy.

DISCUSSION

Up to now the bulk of surgical opinion in this country has looked askance at any suggestion that vagotomy should be substituted for gastrectomy as the operation of choice in chronic duodenal ulcer. This has been due in part to a knowledge of the unpleasant retention phenomena which may develop after it, but is largely the result of conservative prejudice based on the radical departure which it represents from accepted surgical custom. With the memory of the high ulcer-recurrence rate of gastro-enterostomy before them, surgeons have feared lest vagotomy should lead to similar disasters. Such an outlook is, however, no longer justifiable. The unpleasant sequelæ of vagotomy can be prevented by an associated pylorectomy; and an analysis of its after-results during the past seven years shows that the initial duodenal lesion invariably heals, and that ulceration does not recur if neurectomy has been complete and there is no gross gastric retention. Vagotomy is based on sound physiological principles (Beattie 1949). Gastro-enterostomy, on the other hand, was not established on a true physiological foundation. It did not deal radically with the hyperacidity which is the basic factor underlying the ulcer diathesis, and recurrent ulceration was bound to follow it in a high percentage of cases.

Vagotomy, in addition to the other advantages which it possesses over gastrectomy in the treatment of chronic duodenal ulcer, has the asset of enabling an effective surgical attack to be made on the recurrent subacute duodenal lesion. Cases of this type form a not inconsiderable proportion of those with persistent duodenal symptoms despite protracted and intensive medical treatment. Yet many of them never show a definite

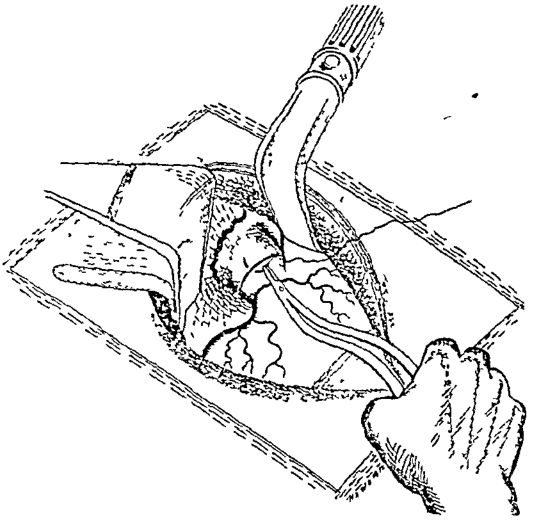

Fig. 6—Suturing of parietal peritoneum over lower œsophagus.

Stay-sutures are passed through the upper and lower borders of the pylorus and serve as retractors during the remainder of the procedure. If carefully placed they will also minimise hæmorrhage by controlling the main pyloric vessels. The general abdominal cavity is then isolated by suitably placed packs and the pyloric sphincter divided (fig. 7). A diamond-shaped segment of the stomach and duodenum, together with the whole anterior portion of the pyloric ring, is removed with scissors introduced through this opening, bleeding points being picked up with mosquito forceps as they arise and tied off subsequently. As much as possible of the scar tissue, together with any anterior ulcer, is excised during this manœuvre (fig. 8). There is often reflux of bile from the duodenum at this stage, which may require energetic use of the sucker to prevent contamination of the surrounding abdominal cavity.

Closure of this gap in the bowel is carried out, as shown in fig. 9, by two continuous intestinal sutures. The first, which is 00 catgut, unites the whole thickness of the duodenum to the gastric mucosa; the second, of no. 1 silk, again picks up the whole thickness of the duodenum and joins it to the muscular and peritoneal layers of the stomach. This forms an overlapping suture line, giving added strength against possible leakage. A final insurance in this respect is achieved by covering the suture line with a free omental graft, secured in position at each end by the stay-sutures. Before the abdomen is closed, the new pyloric opening is carefully tested for patency and size, and a last check made of hæmostasis at the site of the vagotomy.

AFTER-TREATMENT

No special postoperative care is necessary in most cases beyond the usual respiratory exercises advisable after any high abdominal incision; and the protracted gastric suction previously necessary after simple vagotomy is no longer required. Ileus of the stomach and small bowel always occurs and lasts for 24–48 hours, at the end of which time intestinal movements gradually return. But there is usually no gross abdominal distension and little discomfort; hence the patient can start a light Meulengracht type of diet twelve hours after operation. This is rapidly increased so that full normal diet is being eaten on the tenth postoperative day. The avoidance of any form of their previous dietary régime during the early stages of convalescence is, I believe, a major factor in dispelling any remaining "stomach consciousness" in these patients; and experience has shown that early return to normal diet does not delay healing either of the suture line or of any ulcer left behind after pylorectomy.

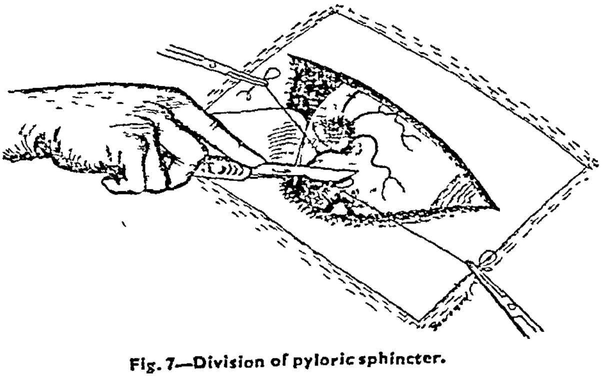

Fig. 7—Division of pyloric sphincter.

In occasional cases ileus is more protracted than usual, and such patients may require gastric suction for a few days before peristalsis returns. The administration of parasympathetic stimulants to hasten this process has not been successful. Though effective in some instances, they have caused severe pain and even collapse in others, so they have now been discarded. If continuous stomach aspiration has to be employed for more than twenty-four hours, intravenous therapy is also instituted; but this is only necessary in such circumstances and never has to be used as a routine postoperative measure.

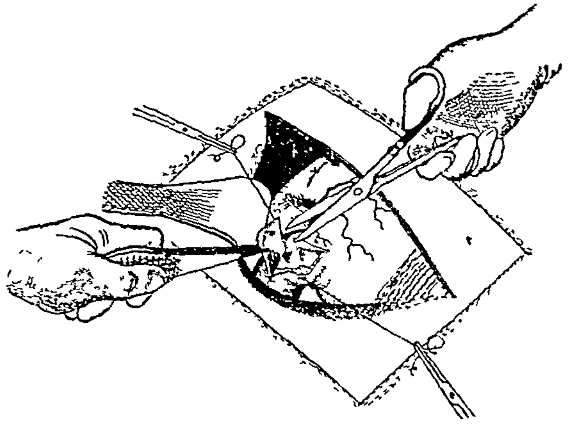

Fig. 8—Partial pylorectomy.

Early ambulation is practised, most patients getting up for the first time after forty-eight hours; the average patient leaves hospital fully ambulant on the twelfth postoperative day. The patients are discharged on a normal dietary régime, except that spirits and condiments are prohibited and smoking limited, until their first review at the outpatient department three months later.

The only unpleasant sequela during early convalescence is temporary dysphagia in over half the cases. This was formerly thought to be due to cardiospasm but is now known to result from partial obstruction of the œsophagus at its passage through the diaphragm, probably as the result of local reaction during healing. It may take place at any time during the first three weeks and usually only lasts a few days. It always passes off spontaneously and is never complete, but may sometimes cause the patient anxiety if he has not been previously warned of its possibility.

RESULTS

The number of vagotomies done by me to the end of 1949 was as follows:

Operation	*No. of cases*
Simple vagotomy	103
Vagotomy and associated gastro enterostomy .	26
Vagotomy and associated pyloroplasty	16
Vagotomy and associated pylorectomy	115
Total ..	260

it is always anticipated that some abscesses will remain open and have to be drained.

However, Sellors (1950) has lately restated his views on the usefulness of penicillin in pulmonary infections, and now says that he has not had to drain an acute lung abscess in the last two years; he recommends 2,000,000 units of penicillin per day in this condition. This is a great departure from his previous views and reflects his experience at our hospital and at the other centres where he works. No pulmonary abscess had been drained at our hospital in the last two years, and it seemed worth while to investigate the situation further.

PRESENT INVESTIGATION

The cases in our survey are those admitted consecutively to the London Chest Hospital from June, 1946, to June, 1949. We excluded those which had resulted from the inhalation of foreign bodies, obstruction by or breakdown of neoplasms, and pulmonary suppurations arising in a bronchiectatic area. We had difficulty in separating the entity "acute abscess," and criteria based on the duration of symptoms were found to be arbitrary. Thus we found that some abscesses, even though they had been present for six months, healed completely with medical treatment. Those which had been present longer than this were excluded, perhaps unnecessarily, from the series.

Samson (1948) states that within six weeks from the onset chronic changes have become established in the pulmonary parenchyma, and that therefore the best time for cure is past. Brock (1942), stating that the abscess should be watched for days not weeks, implies that he regards chronicity as established in the early stages. From the pathological point of view these writers are probably correct. From our cases it appeared that one could, from the clinical point of view, define an "acute" abscess as one which responded to penicillin therapy by complete resolution, and the "chronic" abscess as one which only partially healed. Alternatively, the diagnosis of acute or chronic abscess was retrospective and could only be made at the end of treatment.

INVESTIGATION AND DIAGNOSIS

Investigation and diagnosis were based on the history, physical signs, sputum, radiography, and bronchoscopy.

Onset.—The onset in most of our cases was insidious with no predominant factors of obvious ætiological significance; some cases followed operation. Various periods of general malaise, pyrexia, dry cough, and occasional pains in the chest, were followed by the expectoration of foul purulent sputum, sometimes preceded by small hæmoptyses.

Physical signs were generally scanty and unreliable, those of consolidation being the commonest.

Radiography generally revealed an opacity, with or without a fluid level, localised to one bronchopulmonary segment, though sometimes two adjacent segments appeared to be involved. The radiological appearances were not only important diagnostically but also a most valuable guide to the suitable position for postural drainage.

Bacteriology seemed to be of little importance so far as treatment was concerned, but sputum culture was performed as a routine, and sensitivity of the organisms determined to exclude the possibility of penicillin-resistant infections. In all our cases there was a mixed flora of penicillin-sensitive organisms, consisting mainly of non-hæmolytic streptococci, *Strep. viridans*, *H. influenzæ*, diphtheroids, *N. catarrhalis*, and occasional staphylococci; a few resistant organisms were present among the cultures sometimes. Such a mixed flora has been previously reported by Smith (1948). Anaerobic cultures were not done, and spirochætes and fusiform bacilli were not specially sought since they are penicillin-sensitive.

Bronchoscopy was done as a routine measure early in treatment, more from the diagnostic than the therapeutic aspect, since the presence of radio-translucent foreign bodies and of neoplasms had to be excluded.

TREATMENT

The two basic aims were to overcome the infection and to empty the abscess cavity. In the earlier cases in our series it was expected that these aims would be achieved by surgical drainage, with or without previous penicillin. In the later cases penicillin alone, combined with postural drainage, was used. Some abscesses responded satisfactorily to small doses, and some responded to inhalation therapy alone, but aerosol penicillin is not now being used because we regard the concentrations obtainable as inadequate for most cases. We now regard the optimal dosage of penicillin as 2,000,000 units of the calcium salt a day, given in four intramuscular injections six-hourly. This dosage was usually necessary for not less than three weeks, and seldom for more than four weeks.

After careful determination of the pulmonary segment involved and the best anatomical position for postural drainage, this treatment was given under the supervision of an experienced physiotherapist. It may be emphasised here that postural drainage is not merely a passive affair on the part of the patient—controlled coughing is required to assist drainage—nor is it to be given at long intervals for short periods. In the early days of treatment many hours a day should be spent in the correct posture for maximal drainage, and in some cases it may be possible for the patient to sleep in this position. As the sputum diminishes, six periods of half to three-quarters of an hour may suffice, gradually decreasing till the cavity is finally obliterated. Percussion of the chest wall by the physiotherapist was also most helpful. Bronchoscopic suction and the application of adrenaline swabs have not been required.

General measures, such as good diet, high vitamin intake, iron therapy, and blood-transfusion, according to the severity of the secondary anæmia, were necessary, as in the treatment of all infections. It was also important for the patient to have general physiotherapy, and to be got out of bed and on his feet soon after the initial toxæmia had been combated.

ASSESSMENT OF RESULTS

In assessing results we aimed at the following criteria. Most of the patients should become completely non-toxic in a few days, with rapid diminution of the amount of purulent sputum. By the end of the first week well-marked improvement or even apparent clinical cure should be found; in a fortnight radiological improvement should be visible; and by the fourth week there should be almost complete radiological resolution, or such significant radiological changes as to allow a confident prediction of complete resolution in the near future. If a cavity still exists at this stage the likelihood of a chronic abscess is great. In finally assessing cure, freedom from cough and sputum, normal temperature, radiological healing, and absence of damage to lung parenchyma and bronchi are essential. Bronchograms are performed after maximal radiological clearing has been obtained. Tomograms may be of great assistance in assessing the obliteration of a cavity, and may reveal bronchiectasis at a stage when the lung has not yet completely cleared and bronchograms are undesirable. Follow-up is essential; in most of our cases it has lasted for over a year and it is necessary to keep these patients under observation for considerably longer.

RESULTS

Of 32 acute cases seen in three years 7 have been treated by surgical drainage and 25 with penicillin and postural drainage.

ulcer crater, even after repeated radiography, and are therefore often wrongly labelled as "duodenitis." If, despite his misgivings, a surgeon is prevailed on to operate in such a case, the relatively slight pathological changes present make him justifiably doubtful of the expedience of proceeding to such a drastic measure as subtotal gastrectomy. But these patients often give histories of economic and social disability extending back over many years, and ought not to be denied the benefits resulting from successful surgical intervention. The answer in these circumstances lies in carrying out vagotomy with an associated partial pylorectomy—a relatively minor and non-mutilating procedure about which there need be no such qualms.

CONCLUSION

World-wide experience has now demonstrated, beyond all question, that vagotomy deals effectively and permanently with the basic hyperacidity underlying the ulcer diathesis. The bar to its universal adoption has been the unpleasant retention phenomena which so often follow. But these can be completely eliminated by an associated pylorectomy, and the door is now open for the recognition of vagotomy as the standard surgical procedure for duodenal ulcer. Gastrectomy should in future be reserved for the relatively rare instances where ulceration has penetrated deeply into surrounding viscera, producing complicated lesions which are no longer likely to heal spontaneously after vagotomy.

TREATMENT OF LUNG ABSCESS

A. W. SUTHERLAND
M.B., N.Z., F.R.C.S.
LATE SURGICAL REGISTRAR

L. J. GRANT
M.B. Lond., M.R.C.P.
MEDICAL REGISTRAR

LONDON CHEST HOSPITAL

FOR the last two years it has been felt at the London Chest Hospital that acute lung abscesses could be cured by proper postural drainage and adequate penicillin therapy; surgical drainage appeared to be unnecessary and even obsolete. This impression seemed so definite that it was decided to analyse results over the last three years, thus including a transition period when some cases were still being surgically drained, before the present "medical" regimen came into sole use.

The results of treatment of acute lung abscesses reported in the past have been, with few exceptions, depressingly and uniformly bad. There seemed little to choose between the results of "medical" and "surgical" treatment, each yielding a mortality of about a third. Smith (1948), reviewing 1750 cases collected from published reports, finds a mortality of 34·7% for medically treated and 32·7% for surgically treated cases. The number becoming chronic was considerably higher among the medical ones, and the bad results of surgical treatment were said to be due to delayed operations following over-persistent medical therapy. Before penicillin treatment was developed such therapy could be summarised under the headings of postural drainage, bronchoscopic aspirations, arsenical drugs, and sulphonamides.

Postural Drainage.—We can find no reference to the use of posture alone as a method of treatment.

Bronchoscopy as reported by Allen and Blackman (1936) gave a mortality of 6·5%; of 650 cases 61% were cured and 32·5% remained chronic. Flick et al. (1929) reported a 70% cure-rate in early cases.

Arsenical drugs, though strongly recommended by some (Joannides 1939, Fisher and Finney 1940), are as emphatically condemned by others (Cutler and Gross 1936, Rosenblatt 1940, Sweet 1940).

Sulphonamides were at first believed to hold out great promise, but usually, after early improvement, the cases receiving this treatment developed a well-marked tendency to chronicity (Smith 1948); and D'Ingianni (1944) found a mortality of 58·6% with sulphonamides, compared with 49·1% for his whole group.

SURGICAL DRAINAGE

In contrast with the rather hopeless outlook of the physicians, some surgeons were optimistically preaching the doctrine of early drainage. Brock (1942) urged surgical ("external") drainage at an early stage, preferably in the first few days after diagnosis. Neuhof and Touroff (1940, 1942), operating in the first six weeks, treated 152 cases with a mortality of only 2·6%. However, these figures are rarely attained elsewhere for various reasons. It is contended that the advent of penicillin has encouraged physicians to continue treating cases till the best time for drainage has passed. Surgeons are therefore called in when physicians have failed, and are more often required to deal with chronic abscesses than with acute ones.

PENICILLIN

The rôle of penicillin has been variously estimated, but in general workers have regarded penicillin therapy as inadequate—at best as an accessory to surgery and at worst as an obstacle to cure by delaying drainage beyond the best time. By the end of 1945 Kolmer (1947) had collected a mixed array of 65 cases of pulmonary suppuration, of which 37 were improved or recovered. Smyth and Billingslea (1945) reviewed 31 cases, of which 13 were cured, 8 improved, and 10 not benefited. Stivelman and Kavee (1946) treated 6 cases with penicillin and sulphadiazine, of which 5 completely recovered and 1 became chronic.

These early results were far from conclusive. Sellors (1946) felt that the use of penicillin was not as important as might have been anticipated. In his view the response to systemic and inhalational administration was not marked, and if the abscess did not rupture into a bronchus within a week or so surgical drainage should be considered. More recently greater credit has been given to penicillin as a prophylactic, and it is admitted that it might be of value in preventing the evolution of abscesses in areas of pulmonary infection (Donaldson 1947). However, there is a growing body of opinion that the advent of penicillin has provided not only a prophylactic but also a satisfactory therapy for most cases of lung abscess now being seen. Thus Blades (1947) found in a survey of cases in the U.S. Army that the almost universal use of chemotherapy and later of penicillin in all types of pulmonary infection was partly responsible for the relative rarity of lung abscess, and for the fact that those which did occur were of a less severe and more chronic type, rarely necessitating urgent drainage. Rubin (1947) stated that since the introduction of penicillin the need for surgical intervention had decreased considerably; he recommended doses of 1,000,000 units a day.

The modern view generally held seems to be substantially in agreement with that of Sellors in 1946. Nicholson (1947), Samson (1948), and Lester (1949) all advise a preliminary course of penicillin, and if improvement is not rapid, drainage is the treatment of choice. None of these writers suggest that intensive penicillin therapy has completely taken the place of drainage, since it is always anticipated that some abscesses will remain open and have to be drained.

However, Sellors (1950) has lately restated his views on the usefulness of penicillin in pulmonary infections, and now says that he has not had to drain an acute lung abscess in the last two years; he recommends 2,000,000 units of penicillin per day in this condition. This is a great departure from his previous views and reflects his experience at our hospital and at the other centres where he works. No pulmonary abscess had been drained at our hospital in the last two years, and it seemed worth while to investigate the situation further.

PRESENT INVESTIGATION

The cases in our survey are those admitted consecutively to the London Chest Hospital from June, 1946, to June, 1949. We excluded those which had resulted from the inhalation of foreign bodies, obstruction by or breakdown of neoplasms, and pulmonary suppurations arising in a bronchiectatic area. We had difficulty in separating the entity "acute abscess," and criteria based on the duration of symptoms were found to be arbitrary. Thus we found that some abscesses, even though they had been present for six months, healed completely with medical treatment. Those which had been present longer than this were excluded, perhaps unnecessarily, from the series.

Samson (1948) states that within six weeks from the onset chronic changes have become established in the pulmonary parencyhma, and that therefore the best time for cure is past. Brock (1942), stating that the abscess should be watched for days not weeks, implies that he regards chronicity as established in the early stages. From the pathological point of view these writers are probably correct. From our cases it appeared that one could, from the clinical point of view, define an "acute" abscess as one which responded to penicillin therapy by complete resolution, and the "chronic" abscess as one which only partially healed. Alternatively, the diagnosis of acute or chronic abscess was retrospective and could only be made at the end of treatment.

INVESTIGATION AND DIAGNOSIS

Investigation and diagnosis were based on the history, physical signs, sputum, radiography, and bronchoscopy.

Onset.—The onset in most of our cases was insidious with no predominant factors of obvious ætiological significance; some cases followed operation. Various periods of general malaise, pyrexia, dry cough, and occasional pains in the chest, were followed by the expectoration of foul purulent sputum, sometimes preceded by small hæmoptyses.

Physical signs were generally scanty and unreliable, those of consolidation being the commonest.

Radiography generally revealed an opacity, with or without a fluid level, localised to one bronchopulmonary segment, though sometimes two adjacent segments appeared to be involved. The radiological appearances were not only important diagnostically but also a most valuable guide to the suitable position for postural drainage.

Bacteriology seemed to be of little importance so far as treatment was concerned, but sputum culture was performed as a routine, and sensitivity of the organisms determined to exclude the possibility of penicillin-resistant infections. In all our cases there was a mixed flora of penicillin-sensitive organisms, consisting mainly of non-hæmolytic streptococci, *Strep. viridans*, *H. influenzæ*, diphtheroids, *N. catarrhalis*, and occasional staphylococci; a few resistant organisms were present among the cultures sometimes. Such a mixed flora has been previously reported by Smith (1948). Anaerobic cultures were not done, and spirochætes and fusiform bacilli were not specially sought since they are penicillin-sensitive.

Bronchoscopy was done as a routine measure early in treatment, more from the diagnostic than the therapeutic aspect, since the presence of radio-translucent foreign bodies and of neoplasms had to be excluded.

TREATMENT

The two basic aims were to overcome the infection and to empty the abscess cavity. In the earlier cases in our series it was expected that these aims would be achieved by surgical drainage, with or without previous penicillin. In the later cases penicillin alone, combined with postural drainage, was used. Some abscesses responded satisfactorily to small doses, and some responded to inhalation therapy alone, but aerosol penicillin is not now being used because we regard the concentrations obtainable as inadequate for most cases. We now regard the optimal dosage of penicillin as 2,000,000 units of the calcium salt a day, given in four intramuscular injections six-hourly. This dosage was usually necessary for not less than three weeks, and seldom for more than four weeks.

After careful determination of the pulmonary segment involved and the best anatomical position for postural drainage, this treatment was given under the supervision of an experienced physiotherapist. It may be emphasised here that postural drainage is not merely a passive affair on the part of the patient—controlled coughing is required to assist drainage—nor is it to be given at long intervals for short periods. In the early days of treatment many hours a day should be spent in the correct posture for maximal drainage, and in some cases it may be possible for the patient to sleep in this position. As the sputum diminishes, six periods of half to three-quarters of an hour may suffice, gradually decreasing till the cavity is finally obliterated. Percussion of the chest wall by the physiotherapist was also most helpful. Bronchoscopic suction and the application of adrenaline swabs have not been required.

General measures, such as good diet, high vitamin intake, iron therapy, and blood-transfusion, according to the severity of the secondary anæmia, were necessary, as in the treatment of all infections. It was also important for the patient to have general physiotherapy, and to be got out of bed and on his feet soon after the initial toxæmia had been combated.

ASSESSMENT OF RESULTS

In assessing results we aimed at the following criteria. Most of the patients should become completely non-toxic in a few days, with rapid diminution of the amount of purulent sputum. By the end of the first week well-marked improvement or even apparent clinical cure should be found; in a fortnight radiological improvement should be visible; and by the fourth week there should be almost complete radiological resolution, or such significant radiological changes as to allow a confident prediction of complete resolution in the near future. If a cavity still exists at this stage the likelihood of a chronic abscess is great. In finally assessing cure, freedom from cough and sputum, normal temperature, radiological healing, and absence of damage to lung parenchyma and bronchi are essential. Bronchograms are performed after maximal radiological clearing has been obtained. Tomograms may be of great assistance in assessing the obliteration of a cavity, and may reveal bronchiectasis at a stage when the lung has not yet completely cleared and bronchograms are undesirable. Follow-up is essential; in most of our cases it has lasted for over a year and it is necessary to keep these patients under observation for considerably longer.

RESULTS

Of 32 acute cases seen in three years 7 have been treated by surgical drainage and 25 with penicillin and postural drainage.

ulcer crater, even after repeated radiography, and are therefore often wrongly labelled as "duodenitis." If, despite his misgivings, a surgeon is prevailed on to operate in such a case, the relatively slight pathological changes present make him justifiably doubtful of the expedience of proceeding to such a drastic measure as subtotal gastrectomy. But these patients often give histories of economic and social disability extending back over many years, and ought not to be denied the benefits resulting from successful surgical intervention. The answer in these circumstances lies in carrying out vagotomy with an associated partial pylorectomy—a relatively minor and non-mutilating procedure about which there need be no such qualms.

CONCLUSION

World-wide experience has now demonstrated, beyond all question, that vagotomy deals effectively and permanently with the basic hyperacidity underlying the ulcer diathesis. The bar to its universal adoption has been the unpleasant retention phenomena which so often follow. But these can be completely eliminated by an associated pylorectomy, and the door is now open for the recognition of vagotomy as the standard surgical procedure for duodenal ulcer. Gastrectomy should in future be reserved for the relatively rare instances where ulceration has penetrated deeply into surrounding viscera, producing complicated lesions which are no longer likely to heal spontaneously after vagotomy.

TREATMENT OF LUNG ABSCESS

LONDON CHEST HOSPITAL

For the last two years it has been felt at the London Chest Hospital that acute lung abscesses could be cured by proper postural drainage and adequate penicillin therapy; surgical drainage appeared to be unnecessary and even obsolete. This impression seemed so definite that it was decided to analyse results over the last three years, thus including a transition period when some cases were still being surgically drained, before the present "medical" regimen came into sole use.

The results of treatment of acute lung abscesses reported in the past have been, with few exceptions, depressingly and uniformly bad. There seemed little to choose between the results of "medical" and "surgical" treatment, each yielding a mortality of about a third. Smith (1948), reviewing 1750 cases collected from published reports, finds a mortality of 34·7% for medically treated and 32·7% for surgically treated cases. The number becoming chronic was considerably higher among the medical ones, and the bad results of surgical treatment were said to be due to delayed operations following over-persistent medical therapy. Before penicillin treatment was developed such therapy could be summarised under the headings of postural drainage, bronchoscopic aspirations, arsenical drugs, and sulphonamides.

Postural Drainage.—We can find no reference to the use of posture alone as a method of treatment.

Bronchoscopy as reported by Allen and Blackman (1936) gave a mortality of 6·5%; of 650 cases 61% were cured and 32·5% remained chronic.. Flick et al. (19 reported a 70% cure-rate in early cases.

Arsenical drugs, though strongly recommended by some (Joannides 1939, Fisher and Finney 1940), are as emphatically condemned by others (Cutler and Gross 1936, Rosenblatt 1940, Sweet 1940).

Sulphonamides were at first believed to hold out great promise, but usually, after early improvement, the cases receiving this treatment developed a well-marked tendency to chronicity (Smith 1948); and D'Ingianni (1944) found a mortality of 58·6% with sulphonamides, compared with 49·1% for his whole group.

SURGICAL DRAINAGE

In contrast with the rather hopeless outlook of the physicians, some surgeons were optimistically preaching the doctrine of early drainage. Brock (1942) urged surgical ("external") drainage at an early stage, preferably in the first few days after diagnosis. Neuhof and Touroff (1940, 1942), operating in the first six weeks, treated 152 cases with a mortality of only 2·6%. However, these figures are rarely attained elsewhere for various reasons. It is contended that the advent of penicillin has encouraged physicians to continue treating cases till the best time for drainage has passed. Surgeons are therefore called in when physicians have failed, and are more often required to deal with chronic abscesses than with acute ones.

PENICILLIN

The rôle of penicillin has been variously estimated, but in general workers have regarded penicillin therapy as inadequate—at best as an accessory to surgery and at worst as an obstacle to cure by delaying drainage beyond the best time. By the end of 1945 Kolmer (1947) had collected a mixed array of 65 cases of pulmonary suppuration, of which 37 were improved or recovered. Smyth and Billingslea (1945) reviewed 31 cases, of which 13 were cured, 8 improved, and 10 not benefited. Stivelman and Kavee (1946) treated 6 cases with penicillin and sulphadiazine, of which 5 completely recovered and 1 became chronic.

These early results were far from conclusive. Sellors (1946) felt that the use of penicillin was not as important as might have been anticipated. In his view the response to systemic and inhalational administration was not marked, and if the abscess did not rupture into a bronchus within a week or so surgical drainage should be considered. More recently greater credit has been given to penicillin as a prophylactic, and it is admitted that it might be of value in preventing the evolution of abscesses in areas of pulmonary infection (Donaldson 1947). However, there is a growing body of opinion that the advent of penicillin has provided not only a prophylactic but also a satisfactory therapy for most cases of lung abscess now being seen. Thus Blades (1947) found in a survey of cases in the U.S. Army that the almost universal use of chemotherapy and later of penicillin in all types of pulmonary infection was partly responsible for the relative rarity of lung abscess, and for the fact that those which did occur were of a less severe and more chronic type, rarely necessitating urgent drainage. Rubin (1947) stated that since the introduction of penicillin the need for surgical intervention had decreased considerably; he recommended doses of 1,000,000 units a day.

The modern view generally held seems to be substantially in agreement with that of Sellors in 1946. Nicholson (1947), Samson (1948), and Lester (1949) all advise a preliminary course of penicillin, and if improvement is not rapid, drainage is the treatment of choice. None of these writers suggest that intensive penicillin therapy has completely taken the place of drainage, since

NITROGEN METABOLISM AFTER SURGICAL OPERATIONS

USE OF A PROTEIN HYDROLYSATE AFTER PARTIAL GASTRECTOMY

From the Department of Surgery in the University of Edinburgh and the Clinical Laboratory, Royal Infirmary, Edinburgh

Since 1939 there have been numerous reports on the administration of protein hydrolysates before and after major surgical operations. Among other claims made for these preparations, it was said that with their aid the increased katabolism of protein which regularly follows injury could be largely or entirely prevented. This claim seemed to be unproven, but in some circumstances prevention of the postoperative loss of nitrogen would clearly be of great advantage. In 1946 the Protein Requirements Committee of the Medical Research Council proposed that the value of such hydrolysate therapy should be investigated, and invited us to take part in the investigation. The following report embodies some of the results we obtained in clinical trials on surgical patients.

METHODS

In all the cases a study of nitrogen balance was made involving measurement of the total intake and output of nitrogen in urine, fæces, and gastric aspirations. Though the urinary nitrogen excretion is closely related to the intake of protein and to the previous plane of nitrogen metabolism, two or more days may elapse before changes in protein intake are reflected in the urinary nitrogen excretion. The balance studies were therefore continued from some five days before the operation to ten or more days after it. Instead of pooling urine and fæces for several days, as has been done in many previous investigations, the urinary and fæcal nitrogen excretions were separately estimated every day, to obtain a more precise picture of the changes in nitrogen metabolism. Because of the difficulties involved in the separate collection of urine and fæces in women, men only have been studied.

Food of known caloric and nitrogen contents, estimated from the tables of McCance and Widdowson (1946), was provided from the diet kitchen of the Royal Infirmary, check chemical analyses being made from time to time. Unconsumed food was collected daily, and its nitrogen content was measured and deducted from the amount supplied. Urine, fæces, and gastric aspirations were collected in twenty-four-hour specimens as previously described (Wilkinson et al. 1949). Nitrogen was estimated by the micro-Kjeldahl method.

The nitrogen-balance studies were carried out on patients with peptic ulcer, because it was expected that a high incidence of nutritional disturbance would be found among them; this expectation was not realised. Partial gastrectomy was the commonest major operation in patients suitable for study.

The hydrolysate solution used was 'Casydrol' (Genatosan), prepared by the enzymic digestion of casein with pig's pancreas. This preparation is said to contain all the "essential" amino-acids in suitable proportions. We found that the solution supplied for parenteral injection contained, per 100 ml., 0·656 g. of nitrogen (0·339 g. of amino nitrogen and 0·16 g. of peptide nitrogen), 5·0 g. dextrose, and 0·3 g. of sodium chloride, its pH being 6·5.

FINDINGS IN CONTROLS

In spite of the existence of excellent descriptions of the metabolic disturbances after injury and operation, such as those of Cuthbertson (1936, 1942), it seemed desirable to study these disturbances after the particular operation of partial gastrectomy for peptic ulceration. Indeed, if there was any substance in the suggestion that underlying the "katabolic phase" there might be a pattern of amino-acid requirements and nitrogen excretion specific for different types of injury, it was essential to establish the excretion and metabolic pattern after partial gastrectomy, as Cuthbertson (1936) had done after fractures and operations on bones.

Controls Submitted to Operation

Of the 9 patients in this group, 4 had a partial gastrectomy, and for comparison 5 other patients were chosen of whom 1 was to have a vagotomy, 1 a lumbar sympathectomy, 1 a splanchnicectomy, 1 a subtrochanteric osteotomy of the femur, and 1 a spinal fusion and bone-graft.

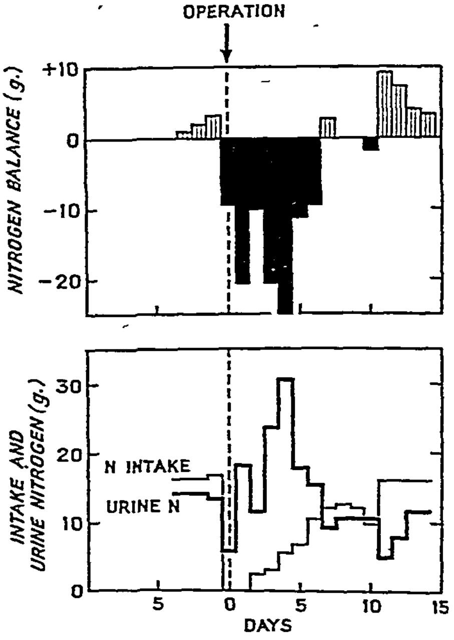

Fig. 1—Nitrogen intake, output, and balance in case 1 submitted to partial gastrectomy.

After partial gastrectomy in well-nourished men there was an increase in the urinary nitrogen excretion (compared with the excretion during the preoperative period) lasting from five to eight days, the greatest loss of nitrogen being between the second and fifth days (fig. 1). Coupled with this increased output of nitrogen there was a reduction in the intake of nitrogen as protein food, which was most marked during the first week after operation but might be severe for up to fourteen days. The resultant of these two factors was a period of negative nitrogen balance lasting from five to eight days or more after operation, the minimum of five or six days being found in those patients whose protein and calorie intake was so rapidly increased as to reach an adequate level (70 g. of protein and 1800 calories daily) within five or six days after operation. In well-nourished patients a still more rapid increase in the food intake after operation did not shorten the katabolic phase below five or six days. On the other hand, delay in restoring an adequate food intake postponed the regaining of a positive nitrogen balance, though it did

RESULTS CLASSIFIED ACCORDING TO OUTCOME

Treatment	No. of cases	Outcome				
		Cured	Becoming chronic	Bronchiectasis symptomless	Bronchiectasis with symptoms	Died
Penicillin, high dosage ..	19	15	2	1	..	1
Penicillin, low dosage ..	6	3	..	1	2	..
Surgical drainage	7	3	..	3	1	..

Of the 7 cases drained the shortest history was of two weeks and the longest twenty weeks, the average history before diagnosis being five and a half weeks. Of the 25 medically treated cases the shortest history was of three weeks and the longest twenty-four weeks, with an average duration of nine and a half weeks.

The results have been classified in the accompanying table according to the ultimate clinical picture. We have found it necessary further to subdivide the medically treated cases into "high penicillin dosage" and "low penicillin dosage" groups, since there seemed to be a considerable difference between those receiving 1,000,000 or more units a day and those receiving less. In the low-dosage group are also included those who had inhalations alone. This "high dosage" scheme is the one which has been in use for the last eighteen months.

The patient who died in the high-dosage group was a diabetic admitted semi-comatose. Despite energetic treatment he passed into irreversible coma and had to be transferred to a general hospital, where he died, possibly of a cerebral abscess (no necropsy was obtained). Since he was never coöperative, effective postural drainage was impossible; penicillin was given for four days only before death, and it might seem almost pedantic to include him in the high-dosage series. It is felt that surgical drainage would not have offered any better prognosis in such a case.

Of the remaining 18 patients in the high-dosage group, 15 were completely cured, 2 became chronic in so far as they improved dramatically with abolition of constitutional symptoms and considerable diminution of sputum, but with radiological evidence of small residual cavities. One of these patients had a history of an extremely severe infection, and the other had had "low dosage" previously and had not been vigorously attacked from the outset. These patients were rapidly made fit for lobectomy, and at no time did their condition give rise to anxiety. Finally, 1 case gave radiological evidence of residual localised bronchiectasis. Whether this will cause symptoms owing to reinfection at a later date or not it is impossible to predict. This development of localised bronchiectasis is not confined to those healed medically. Of the 7 cases treated by early drainage 3 are clinically cured but have a residual symptomless bronchiectasis, and 1 other has a severe bronchiectasis involving only the area of the previous abscess in the upper lobe, with a copious purulent sputum.

Of the 6 patients in the low-dosage group only 3 were completely cured; the other 3 patients have a residual bronchiectasis, 2 producing symptoms, and 1 symptom-free.

A further consideration in the assessment of the results is the duration of disability. In the cases surgically drained the average duration of postoperative drainage before healing was twenty-eight weeks. For most of this time, certainly, the patients were out of hospital, some at work, and attending once a week for adjustment of the tube. Nevertheless this period represents a long, and, at the best, an uncomfortable and unpleasant time for the patient. The patients treated medically were out of hospital (except the 2 coming to resection) within four weeks, cured and ready for work. Even the 2 patients who had a resection were completely recovered and back at work, with the certainty of a cure, before this period had elapsed.

CONCLUSIONS

Even from this small series of cases it seems that penicillin and postural drainage can completely cure lung abscesses. The results obtained with the high-dosage scheme appear to be superior to those in the other groups. It may well be that the classification of lung abscess into acute and chronic is, from the clinical point of view, undesirable, and that all cases, whatever their duration, ought to be treated along these lines. The abscesses now being seen seem to be, on the whole, more indolent than those hitherto described, probably owing to the administration of sulphonamides and antibiotics, often in inadequate doses. These doses control the infection only partially, so that the whole pathological process is slowed down but not arrested. Diagnosis is therefore rarely possible at an early stage, and the general exhortation to drain early cannot often be implemented. This may very well explain the poor results obtained by drainage. Moreover, persistence with inadequate medical treatment itself predisposes to chronicity in so far as resistant strains of organisms are allowed to develop.

One of our chronic cases which came to lobectomy and 6 of the 7 which were drained had previously had inadequate medical treatment. It seems that the immediate institution of treatment with 2,000,000 units of penicillin a day and postural drainage is the safest course to follow; this obviates surgical drainage and promises the greatest freedom from immediate and remote complications. We feel that as energetic postural drainage and high penicillin dosage become increasingly used, surgical drainage will be regarded as obsolete; chronic complications will be minimised and those that arise will be readily curable by radical, not palliative, surgery, carried out on patients who are in the best condition to receive it.

SUMMARY

Recent tendencies in the treatment of lung abscess are reviewed.

Of 32 consecutive cases of acute lung abscess, 25 were treated by postural drainage and penicillin alone; the penicillin therapy is divided into "high dosage" and "low dosage" groups.

The numbers cured were: 15 out of 19 cases in the high-dosage group; 3 out of 6 in the low-dosage group; and 3 out of 7 cases surgically drained.

It is suggested that there is no place for surgical drainage of acute lung abscesses. They will heal under intensive medical treatment, and local complications, if any, will be treated by resection.

We wish to thank Mr. T. Holmes Sellors and Mr. Vernon Thompson for their suggestion to review these cases; the physicians of the London Chest Hospital for giving us access to the patients and records; and our colleagues who have so kindly given advice and help.

Continued at foot of next page

or protein-components in the body, it seemed worth while to find out whether this response to injury in man could be modified after operation by varying the protein and calorie intake.

EFFECTS OF INTRAVENOUS CASEIN HYDROLYSATE

It seemed unlikely that the katabolic phase would be affected by an intake less than that necessary for nitrogen equilibrium. Accordingly it was decided to maintain throughout the postoperative period a daily intake equivalent to 11 g. of nitrogen, administering protein hydrolysate and glucose solution by intravenous infusion until food could be eaten in sufficient quantities. The hydrolysate (casydrol) was injected at a rate of 500 ml. in three to five hours, 2–3 litres being given in each twenty-four hour period for up to four or five days after operation. These volumes of casydrol provided 80–120 g. of protein (12·8–19·2 g. of nitrogen) and 100–150 g. of glucose—i.e., up to 1080 calories, of which rather more than half was derived from carbohydrate.

After gastrectomy 4 patients each received a total of 43–70 g. of nitrogen in the form of casydrol infusions in addition to ordinary food. The accompanying table shows some of the data derived from these patients and allows comparison with the controls and with 3 other patients receiving a milk mixture. Fig. 4 shows in detail the nitrogen metabolism of one of these patients.

In the table the total postoperative period, from operation to the return of stabilised protein metabolism, has been reckoned as ten days, and the period during which the urinary nitrogen excretion is much increased as six days. In both the six-day and ten-day periods all the patients given casydrol for the first few days after gastrectomy excreted more nitrogen in their urine than the controls. Comparison of the ten-day urine nitrogen excretions in case 1 (control gastrectomy) and in cases 2–5 (receiving casydrol) shows that this additional nitrogen excreted was nearly equivalent to the quantity of nitrogen injected as casydrol. The increase in urinary nitrogen was greatest in the first seven days, as is clearly illustrated in fig. 4 (case 2), and the intravenous infusion was associated with a well-marked increase rather than with a reduction in urinary nitrogen. In this particular case the postoperative daily urinary nitrogen excretion remained higher than before operation for more than two weeks, and this was probably due to superficial venous thrombosis which developed in the second postoperative week.

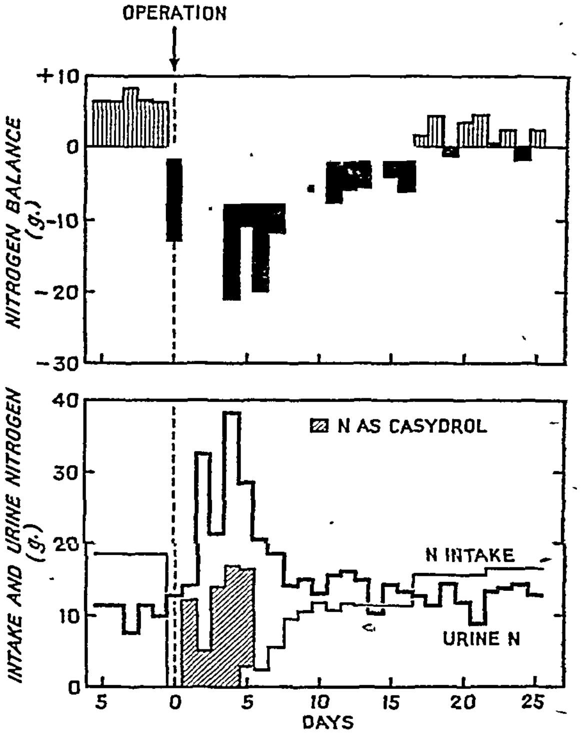

Fig. 4—Nitrogen balance, intake, and output before and after partial gastrectomy for duodenal ulcer in case 2, who was given intravenous hydrolysate for five days after operation.

Compared with other patients, those given casydrol intravenously had poorer appetites and consumed less food during the period of the casydrol infusion, and this affected their total daily calorie intake. In case 4 the calorie intake remained below 1000 a day throughout the infusion period, but in the other 3 cases the intake was 1000–1500 calories a day except on occasional single days. For the first day or two after the infusion was stopped, both protein and calorie intakes fell, but urinary nitrogen excretion continued at a high rate, and a considerable nitrogen loss resulted. In general, however, when the oral intake of food was restarted, it was possible to increase the daily quantities rapidly; nevertheless these patients were several days later in achieving nitrogen equilibrium. Hence the intravenous administration of

* One specimen of urine lost, probably containing about 15 g. of nitrogen.
The postoperative periods, 0–6 days or 0–10 days, include the day of operation and the succeeding 5 or 9 days.

not alter the duration of the postoperative rise in urinary nitrogen excretion.

There are important exceptions to this general rule. In a few cases the expected big increase in urinary nitrogen on the second or third day after operation did not occur; this seemed to be associated either with undernourishment or with relatively slight trauma. The relative absence of a katabolic phase in such cases may thus be due to the patient's inability to respond to the stimulus of trauma because of existing protein depletion, or to an insufficient stimulus, or to both these factors. In assessing these possibilities the preoperative period of study is of great importance, for it indicates the level of nitrogen excretion on a particular intake of protein and calories. The urinary nitrogen excretion was increased by complications such as wound infection, bronchopneumonia and other pulmonary complications, and superficial phlebitis.

From our own findings and those published in the United States and Canada, a postoperative daily intake of at least 70 g. of protein (11 g. of nitrogen) and 1800 calories seems to be necessary for the attainment of nitrogen equilibrium. After gastrectomy the restriction of food intake varies widely in degree and duration. In the surgical charge in which the present studies were made the intake was usually similar to that shown in case 1 (fig. 1), unless some disturbance compelled modification. To define how far the postoperative changes in nitrogen metabolism may be attributed to dietary restriction further control experiments were done.

Controls Starved but not Submitted to Operation

Four healthy male medical students volunteered to act as subjects. None was actively growing, all were well-nourished though varying widely in physical type, and all were younger than most of the patients submitted to operation.

In experiment A (3 subjects) the daily calorie intake was maintained at 2500 throughout. An initial daily protein intake of 90 g. (14·4 g. of nitrogen) was reduced to 10 g. of protein (1·6 g. of nitrogen) on the day of the hypothetical operation and the next two days; this incomplete protein starvation was designed to make the experiment less rigorous and unpleasant and to allow greater variety and palatability in the diet. From the fourth day onwards the protein intake was increased as nearly as possible at the same rate as in case 1; but a somewhat higher intake of both protein and calories was achieved in the controls than in the patients submitted to operation.

In experiment B (3 subjects) the preliminary period was similar, but for three days, starting on the day of the imaginary operation, the calorie intake was reduced to 500 a day and the protein to 10 g. a day. Thereafter calories were increased step by step with the protein until the original intake of both was regained. The amount of 500 calories a day was chosen because it is the equivalent of the glucose present in 2500 ml. of 5% glucose solution, the commonly accepted desirable maximum of daily fluid to be administered intravenously. During the fast activity was limited, the subjects spending most of the day in bed but rising to defæcate; activity was later gradually increased to normal. The water intake was not limited.

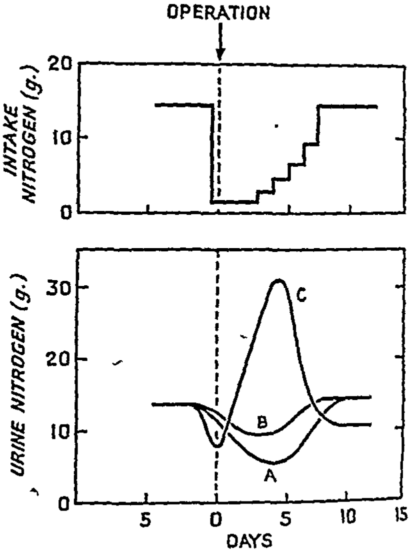

Fig. 3—Smoothed curves to show variations in urinary nitrogen excretion in controls submitted to dietary restrictions but not to operation (A and B), and in case 1 submitted to gastrectomy (C).

The results of both experiments in one subject are shown in fig. 2 and are typical of the two groups. When both calories and protein were restricted, the amount of nitrogen excreted daily in the urine fell from the previous 13–14 g. to 8–10 g., but rose again towards the initial level as food intake was increased from the third day onwards. When protein only was restricted there was a greater reduction in urinary nitrogen to 5 or 6 g. a day, and as the protein intake was increased the urinary nitrogen also increased. In no case in either experiment did the daily urinary excretion of nitrogen rise above the "preoperative" level. Nevertheless, it is important to note that the nitrogen balance was negative while the protein intake was low.

In fig. 3 the amounts of urinary nitrogen excreted in the two control experiments without operation and in case 1 are compared. In each kind of starvation the urinary nitrogen fell at a time when the patient submitted to partial gastrectomy combined with starvation showed a well-marked rise. It seems reasonable to conclude that, whereas the difference between the lower two curves is related to the protein spared by the maintenance of the calorie intake, the difference between the upper two curves reflects the protein katabolism resulting from partial gastrectomy in a well-nourished person. It is also evident that the quantity of nitrogen excreted in the urine is a more direct criterion of nitrogen metabolism than is nitrogen balance.

In the belief that the additional urinary nitrogen was derived from the breakdown of protein tissue, or from stores of protein

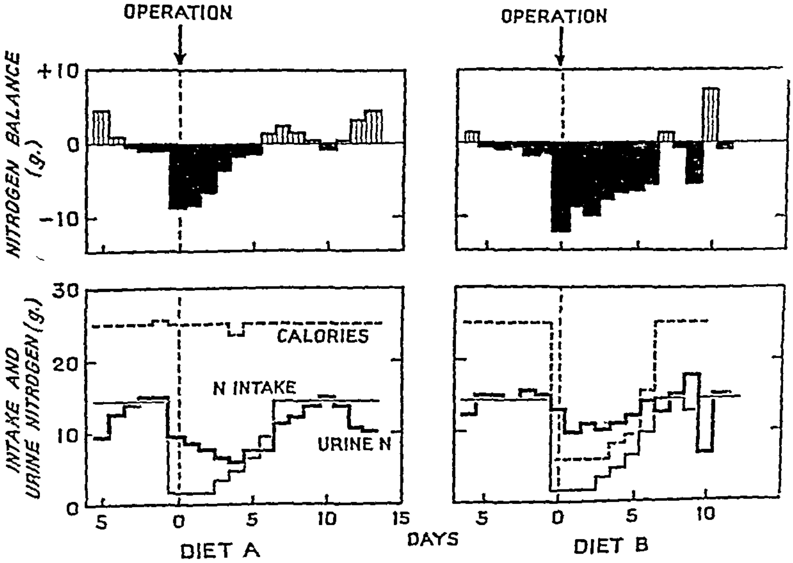

Fig. 2—Controls A and B showing variation in urinary nitrogen on the two types of diet. In this figure the "operation" is imaginary.

or protein-components in the body, it seemed worth while to find out whether this response to injury in man could be modified after operation by varying the protein and calorie intake.

EFFECTS OF INTRAVENOUS CASEIN HYDROLYSATE

It seemed unlikely that the katabolic phase would be affected by an intake less than that necessary for nitrogen equilibrium. Accordingly it was decided to maintain throughout the postoperative period a daily intake equivalent to 11 g. of nitrogen, administering protein hydrolysate and glucose solution by intravenous infusion until food could be eaten in sufficient quantities. The hydrolysate (casydrol) was injected at a rate of 500 ml. in three to five hours, 2–3 litres being given in each twenty-four hour period for up to four or five days after operation. These volumes of casydrol provided 80–120 g. of protein (12·8–19·2 g. of nitrogen) and 100–150 g. of glucose—i.e., up to 1080 calories, of which rather more than half was derived from carbohydrate.

After gastrectomy 4 patients each received a total of 43–70 g. of nitrogen in the form of casydrol infusions in addition to ordinary food. The accompanying table shows some of the data derived from these patients and allows comparison with the controls and with 3 other patients receiving a milk mixture. Fig. 4 shows in detail the nitrogen metabolism of one of these patients.

In the table the total postoperative period, from operation to the return of stabilised protein metabolism, has been reckoned as ten days, and the period during which the urinary nitrogen excretion is much increased as six days. In both the six-day and ten-day periods all the patients given casydrol for the first few days after gastrectomy excreted more nitrogen in their urine than the controls. Comparison of the ten-day urine nitrogen excretions in case 1 (control gastrectomy) and in cases 2–5 (receiving casydrol) shows that this additional nitrogen excreted was nearly equivalent to the quantity of nitrogen injected as casydrol. The increase in urinary nitrogen was greatest in the first seven days, as is clearly illustrated in fig. 4 (case 2), and the intravenous infusion was associated with a well-marked increase rather than with a reduction in urinary nitrogen. In this particular case the postoperative daily urinary nitrogen excretion remained higher than before operation for more than two weeks, and this was probably due to superficial venous thrombosis which developed in the second postoperative week.

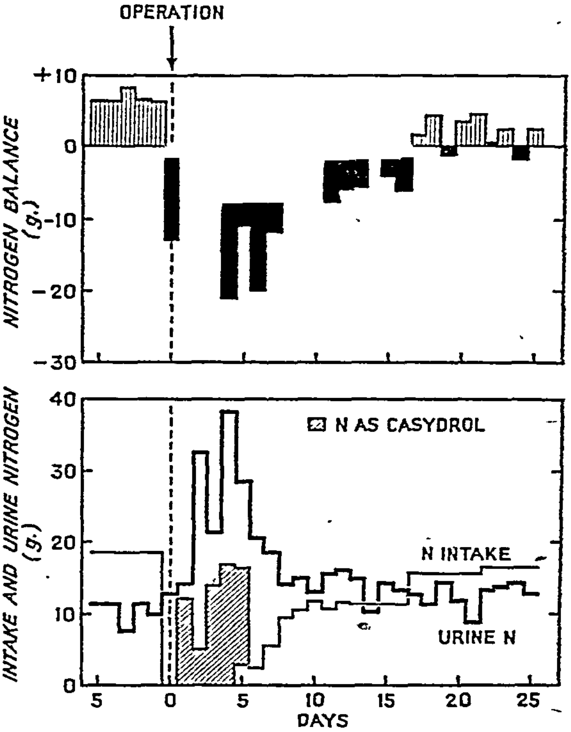

Fig. 4—Nitrogen balance, intake, and output before and after partial gastrectomy for duodenal ulcer in case 2, who was given intravenous hydrolysate for five days after operation.

Compared with other patients, those given casydrol intravenously had poorer appetites and consumed less food during the period of the casydrol infusion, and this affected their total daily calorie intake. In case 4 the calorie intake remained below 1000 a day throughout the infusion period, but in the other 3 cases the intake was 1000–1500 calories a day except on occasional single days. For the first day or two after the infusion was stopped, both protein and calorie intakes fell, but urinary nitrogen excretion continued at a high rate, and a considerable nitrogen loss resulted. In general, however, when the oral intake of food was restarted, it was possible to increase the daily quantities rapidly; nevertheless these patients were several days later in achieving nitrogen equilibrium. Hence the intravenous administration of

* One specimen of urine lost, probably containing about 15 g. of nitrogen.
The postoperative periods, 0–6 days or 0–10 days, include the day of operation and the succeeding 5 or 9 days.

casydrol had increased the daily urinary nitrogen excretion, had increased the duration of excessive nitrogen excretion, and had so impaired appetite that the re-establishment of normal feeding was delayed, with the result that the period of negative nitrogen balance was prolonged.

The failure to maintain an adequate intake of calories might be an important factor in these results. The daily administration of a volume of 5% glucose solution sufficient to achieve, together with the casydrol, an intake of 1800 calories would have involved the infusion of another 4 litres of fluid, making a total of 6–7 litres per twenty-four hours. This was obviously undesirable; and moreover the use of hypertonic glucose solution in sufficient quantities leads either to loss of the injected glucose by urinary excretion or to an excessive incidence of venous thrombosis. The possibility of providing a supply of calories by injecting a glucose solution across the gastrojejunal stoma into the jejunum during the infusion of casydrol was then considered. As a preferable development of this idea, it was decided to provide both protein and calories by injecting a high-protein, high-calorie mixture (milk mixture) into the jejunum.

EFFECTS OF INTRAJEJUNAL OR ORAL MILK MIXTURE

In this group there were 6 patients who during the postoperative katabolic phase received, initially through a double-lumen tube inserted at operation into the distal limb of the jejunum and later by mouth, a mixture of whole milk, dried skimmed milk, and lactose. The mixture was prepared by adding to a pint of whole milk 120 g. of dried skimmed-milk powder, 100 g. of lactose, and sufficient water to ensure complete solution of the milk powder and lactose. These quantities provide 60 g. of protein, 23 g. of fat, and 187 g. of carbohydrate, sufficient to yield 1200 calories.

In 3 of the 6 patients the objective of maintaining an intake of more than 70 g. of protein and 1800 calories a day throughout the postoperative period was nearly achieved. The three failures were purely technical; too little mixture was injected in one; in another the large fæcal loss of nitrogen must have greatly reduced the nitrogen available for absorption; and in the third a blockage of the tube interfered with intake.

After operation, in all these patients, in spite of the large provisions of protein and calories, there was an increase in urinary nitrogen excretion, which, however, occurred a day or two later than in the patients of the previous groups (fig. 5). On the other hand, there was a much less severe negative nitrogen balance. These cases show that, even when the calorie intake is about 1800 a day, the daily administration of 70 g. of protein will not prevent the postoperative increase in urinary nitrogen excretion. However, it is evident that the jejunal instillation of whole protein accompanied by an adequate quantity of carbohydrate is less wasteful than the intravenous administration of a protein hydrolysate with inadequate quantities of glucose.

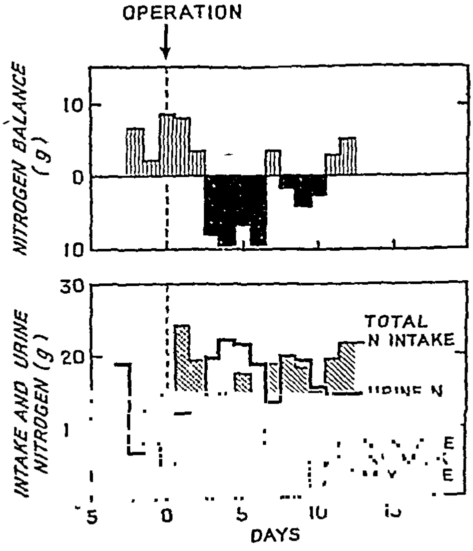

Fig. 5—Nitrogen balance, intake, and output in case 6, who was given milk mixture after partial gastrectomy.

DISCUSSION

The present investigation on well-nourished patients who had undergone partial gastrectomy has shown that an increased urinary nitrogen excretion begins on the second day after operation and lasts from five to eight days, the greatest loss being between the second and fifth days. This increase in urinary nitrogen can be resolved into three fractions: (1) due to starvation for protein; (2) due to the restriction of calorie intake: and (3) a major fraction related in some way to the operation injury. This third fraction seems also to be related directly to the initial total mass of body protein, which in turn is governed by the preceding state of protein nutrition together with factors such as previous disease.

That some part of the "katabolic phase" is due to injury and the subsequent recovery process is strongly suggested by its constant occurrence in well-nourished patients, irrespective of the food intake during the immediate postoperative period. The excessive breakdown of protein which constitutes the katabolic phase and is shown by an increased urinary nitrogen excretion rather than by a negative nitrogen balance has been found after injury and disease of the most varied kinds and in species other than man; it is not abolished by the intake of protein, even when the protein is adequately protected by carbohydrate, and is much less evident or even absent in undernourished persons with little or no protein available for katabolism. These considerations inevitably raise the question whether the katabolic phase is a pathological phenomenon to be combated by forced feeding or constitutes a fundamental biological reaction to injury. In the latter case it should be considered that the katabolic phase may even be a valuable reaction and ought not to be interfered with; at least it is associated in time with great reparative activity, it appears to do no harm, and it cannot be abolished by normal feeding methods.

SUMMARY

After partial gastrectomy and other surgical operations of similar severity in well-nourished persons there is an absolute increase in the daily excretion of nitrogen in the urine; this lasts from five to eight days, the greatest loss being between the second and fifth days.

The administration of protein (as such) or of protein hydrolysate intravenously during this period merely increases the urinary nitrogen proportionately and does not modify the "katabolic phase" in any essential way.

This increased urinary excretion does not occur in persons who are deprived of food protein but do not undergo surgical operation.

There is a negative nitrogen balance during the postoperative period, irrespective of the protein intake, and in persons who receive little or no protein but are not submitted to surgical operation.

Hence the postoperative change in protein metabolism is due partly to the usual reduction in food intake and partly to an increased protein katabolism which is inseparably associated with injury. The latter factor, the important part of the "katabolic phase," is most clearly demonstrated by the postoperative increase in urinary nitrogen rather than by the negative nitrogen balance.

We wish to thank Sir James Learmonth for providing clinical facilities and for his continued interest in the work; the four student volunteers in the control experiments; the dietitians who provided the diets; and the nurses without whose coöperation these studies would have been impossible. A grant was made to one of us (C. P. S.) by the Medical Research Council for technical assistance and materials; and one of us (A. W. W.) held the Syme Surgical Fellowship of Edinburgh University during these studies.

PRINCE OF WALES'S HOSPITAL, LONDON

In the U.S.A., where it is estimated that 2,500,000–3,000,000 children are vaccinated against whooping-cough annually, transient, serious, and even fatal neurological complications have recently been described following the inoculations. In the case reported here the child developed signs of severe cerebral damage shortly after the first inoculation with combined diphtheria-pertussis antigens. We have found only one other example of such sequelæ reported in this country (*British Medical Journal* 1949, 1950). This was a fatal case in a male infant, a twin, aged 8 months. The twins received their first dose of diphtheria-pertussis prophylactic in the morning. At 6 P.M. the boy began to cry and make strange movements with one arm. He was taken to hospital at 1.30 A.M. next day, and died an hour later. Death was ascribed to idiosyncrasy to the pertussis vaccine.

Madsen (1933), in the U.S.A., reported the death in convulsions of two newborn infants after a second injection of pertussis vaccine. Necropsy did not reveal the cause of death.

Doull et al. (1936) reported 3 cases of children with transient convulsions in a series of 496 immunisations with fluid pertussis vaccine. Taylor (1938) recorded a reaction in a boy aged 10 months who after a second dose of pertussis vaccine developed "tonic convulsions of the feet, subnormal temperature, and limpness of the legs." Transient convulsions were noted in a child by Kendrick and Eldering (1939), and in 2 children by Sako et al. (1945). Werne and Garrow (1946) reported the death of identical twins in shock sixteen and twenty-four hours after a second combined diphtheria-pertussis inoculation; autopsy showed "lesions consistent with death in anaphylactic shock with acute vascular injury as the underlying cause." This is the first paper in which the morbid anatomy has been described. Brody (1947) reported 2 cases. The first was in a boy aged 10 months who developed transient acute neurological symptoms, resembling a demyelinating lesion, after injections of pertussis vaccine. Symptoms occurred after each of four injections and at decreasing intervals. Subsequent intradermal injection of the vaccine led to generalised paralysis, dysphagia, and respiratory difficulty, and the child died of bronchopneumonia. The second case was in a child of 7 months who developed convulsions after each of three injections of pertussis vaccine, with resultant severe mental deterioration; pneumo-encephalograms showed cortical atrophy. Byers and Moll (1948) found 15 cases on scrutiny of ten years' records of admissions to the Boston Children's Hospital; of these, 1 child recovered completely, 2 died, and autopsy on 1 showed "diffuse atrophy and gliosis of the brain"; 9 showed residual cerebral damage (5 had hemiplegia and 2 were virtually decerebrate); and 3 were under observation for too short a period for final assessment. Since the publication of this paper Byers (personal communication) has seen several more cases. Toomey (1949) reported 38 cases of convulsions following prophylactic pertussis vaccination which were collected after an appeal through American pædiatric journals and from a questionnaire sent to a large number of pædiatricians. In 25 of these there was sufficient detail for analysis; 2 had died, and the rest fully recovered. Globus and Kohn (1949) report 2 cases: one child was left with severe mental damage from which he is making a very slow recovery; the other declined progressively until death.

CASE-RECORD

A boy, born on June 6, 1946, was the second child of a twin delivery (uniovular). This was a first pregnancy, and delivery was spontaneous and rapid, the second stage lasting an hour. There was no evidence of compression of the skull, asphyxia, or distress. The child was normal in health and development until the age of 2 years 4 months, when he was admitted to hospital on Oct. 3, 1948, because of a generalised convulsion. This passed off rapidly but left him with a transient right hemiplegia, from which he fully recovered in five hours, and he was discharged from hospital next day. At the time of this illness three other children in the same house were suffering from mumps, and he was diagnosed as a case of mumps encephalitis. No investigations were carried out.

On Jan. 16, 1949, at the age of 2 years 7 months, the twins were immunised with combined diphtheria-pertussis antigens. One twin remained well, but the patient developed a generalised convulsion thirty-six hours later and was admitted to hospital.

On admission, on Jan. 18, he was comatose, and his temperature was subnormal but soon rose to 101·8°F. The coma deepened, and a few hours later there were further generalised convulsions. There was no neck rigidity or Kernig's sign. The pupils were small and equal, and there was a doubtful reaction to light. The fundi were normal. The conjunctival, abdominal, and cremasteric reflexes were absent, the deep reflexes were brisk, and there were bilateral extensor plantar responses. The heart and lungs were clinically normal. The cerebrospinal fluid (C.S.F.) contained 2 lymphocytes and 21 red cells per c.mm., protein 25 mg. per 100 ml. (globulin not increased); chlorides 720 mg. and sugar 18 mg. per 100 ml. (not collected in a fluoride tube). No organisms were found. The urine was acid and contained a trace of albumin, no sugar, some acetone, and chlorides 2 g. per litre. The convulsions were controlled with intramuscular sodium phenobarbitone gr. 1. Glucose in saline solution was given rectally.

Jan. 19: the child's clinical condition remained the same. His blood-sugar was 156 mg. and blood-urea 107 mg. per 100 ml.

Jan. 20: His temperature was normal. He was in a deep sleep and was roused with difficulty. He yawned frequently. The white-cell count was 11,000 per c.mm. (polymorphs 51%, lymphocytes 32%, monocytes 14%, eosinophils 1%). Lumbar puncture was repeated; the C.S.F. was clear, under a pressure of 25 cm. of H_2O, and contained 4 cells per c.mm. (2 red cells, 1 lymphocyte, and 1 polymorph), protein 30 mg. per 100 ml. (no increase of globulin), chlorides 720 mg. and sugar 95 mg. per 100 ml.; blood-urea 87 mg. and serum-calcium 2 mg. per 100 ml.; alkali reserve 50 vols CO_2%. Wassermann reaction negative.

Jan. 21: a right hemiplegia had developed and speech was lost completely.

Aug. 5 (age 3 years 2 months): radiograms of the skull showed no abnormality. A lumbar encephalogram showed much dilatation of the left lateral ventricle (figs. 1–4).

Oct. 12: electro-encephalogram showed diminished electrical activity of the left cerebral hemisphere (fig. 5).

State on discharge (Jan. 8, 1950, at the age of 3 years 7 months).—Some speech had returned, and he had a vocabulary of about ten words. He was progressing mentally, understood much of routine living, and was coöperative in the ward, though given to tantrums. He played with other children but with little sense of coöperation. The right arm and leg casydrol had increased the daily urinary nitrogen excretion, had increased the duration of excessive nitrogen excretion, and had so impaired appetite that the re-establishment of normal feeding was delayed, with the result that the period of negative nitrogen balance was prolonged.

The failure to maintain an adequate intake of calories might be an important factor in these results. The daily administration of a volume of 5% glucose solution sufficient to achieve, together with the casydrol, an intake of 1800 calories would have involved the infusion of another 4 litres of fluid, making a total of 6–7 litres per twenty-four hours. This was obviously undesirable; and moreover the use of hypertonic glucose solution in sufficient quantities leads either to loss of the injected glucose by urinary excretion or to an excessive incidence of venous thrombosis. The possibility of providing a supply of calories by injecting a glucose solution across the gastrojejunal stoma into the jejunum during the infusion of casydrol was then considered. As a preferable development of this idea, it was decided to provide both protein and calories by injecting a high-protein, high-calorie mixture (milk mixture) into the jejunum.

EFFECTS OF INTRAJEJUNAL OR ORAL MILK MIXTURE

In this group there were 6 patients who during the postoperative katabolic phase received, initially through a double-lumen tube inserted at operation into the distal limb of the jejunum and later by mouth, a mixture of whole milk, dried skimmed milk, and lactose. The mixture was prepared by adding to a pint of whole milk 120 g. of dried skimmed-milk powder, 100 g. of lactose, and sufficient water to ensure complete solution of the milk powder and lactose. These quantities provide 60 g. of protein, 23 g. of fat, and 187 g. of carbohydrate, sufficient to yield 1200 calories.

In 3 of the 6 patients the objective of maintaining an intake of more than 70 g. of protein and 1800 calories a day throughout the postoperative period was nearly achieved. The three failures were purely technical; too little mixture was injected in one; in another the large fæcal loss of nitrogen must have greatly reduced the nitrogen available for absorption; and in the third a blockage of the tube interfered with intake.

After operation, in all these patients, in spite of the large provisions of protein and calories, there was an increase in urinary nitrogen excretion, which, however, occurred a day or two later than in the patients of the previous groups (fig. 5). On the other hand, there was a much less severe negative nitrogen balance. These cases show that, even when the calorie intake is about 1800 a day, the daily administration of 70 g. of protein will not prevent the postoperative increase in urinary nitrogen excretion. However, it is evident that the jejunal instillation of whole protein accompanied by an adequate quantity of carbohydrate is less wasteful than the intravenous administration of a protein hydrolysate with inadequate quantities of glucose.

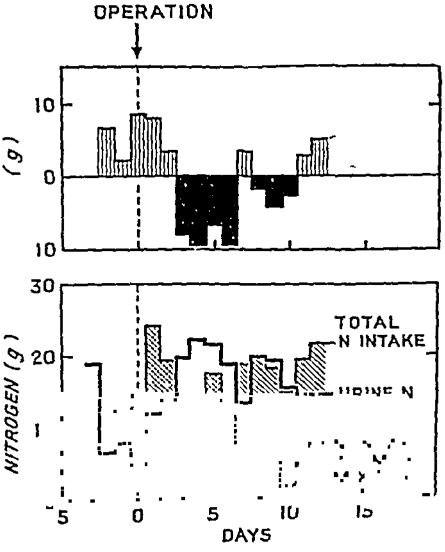

Fig. 5—Nitrogen balance, intake, and output in case 6, who was given milk mixture after partial gastrectomy.

DISCUSSION

The present investigation on well-nourished patients who had undergone partial gastrectomy has shown that an increased urinary nitrogen excretion begins on the second day after operation and lasts from five to eight days, the greatest loss being between the second and fifth days. This increase in urinary nitrogen can be resolved into three fractions: (1) due to starvation for protein; (2) due to the restriction of calorie intake; and (3) a major fraction related in some way to the operation injury. This third fraction seems also to be related directly to the initial total mass of body protein, which in turn is governed by the preceding state of protein nutrition together with factors such as previous disease.

That some part of the "katabolic phase" is due to injury and the subsequent recovery process is strongly suggested by its constant occurrence in well-nourished patients, irrespective of the food intake during the immediate postoperative period. The excessive breakdown of protein which constitutes the katabolic phase and is shown by an increased urinary nitrogen excretion rather than by a negative nitrogen balance has been found after injury and disease of the most varied kinds and in species other than man; it is not abolished by the intake of protein, even when the protein is adequately protected by carbohydrate, and is much less evident or even absent in undernourished persons with little or no protein available for katabolism. These considerations inevitably raise the question whether the katabolic phase is a pathological phenomenon to be combated by forced feeding or constitutes a fundamental biological reaction to injury. In the latter case it should be considered that the katabolic phase may even be a valuable reaction and ought not to be interfered with; at least it is associated in time with great reparative activity, it appears to do no harm, and it cannot be abolished by normal feeding methods.

SUMMARY

After partial gastrectomy and other surgical operations of similar severity in well-nourished persons there is an absolute increase in the daily excretion of nitrogen in the urine; this lasts from five to eight days, the greatest loss being between the second and fifth days.

The administration of protein (as such) or of protein hydrolysate intravenously during this period merely increases the urinary nitrogen proportionately and does not modify the "katabolic phase" in any essential way.

This increased urinary excretion does not occur in persons who are deprived of food protein but do not undergo surgical operation.

There is a negative nitrogen balance during the postoperative period, irrespective of the protein intake, and in persons who receive little or no protein but are not submitted to surgical operation.

Hence the postoperative change in protein metabolism is due partly to the usual reduction in food intake and partly to an increased protein katabolism which is inseparably associated with injury. The latter factor, the important part of the "katabolic phase," is most clearly demonstrated by the postoperative increase in urinary nitrogen rather than by the negative nitrogen balance.

We wish to thank Sir James Learmonth for providing clinical facilities and for his continued interest in the work; the four student volunteers in the control experiments; the dietitians who provided the diets; and the nurses without whose coöperation these studies would have been impossible. This is the first paper in which the morbid anatomy has been described. Brody (1947) reported 2 cases. The first was in a boy aged 10 months who developed transient acute neurological symptoms, resembling a demyelinating lesion, after injections of pertussis vaccine. Symptoms occurred after each of four injections and at decreasing intervals. Subsequent intradermal injection of the vaccine led to generalised paralysis, dysphagia, and respiratory difficulty, and the child died of bronchopneumonia. The second case was in a child of 7 months who developed convulsions after each of three injections of pertussis vaccine, with resultant severe mental deterioration; pneumoencephalograms showed cortical atrophy. Byers and Moll (1948) found 15 cases on scrutiny of ten years' records of admissions to the Boston Children's Hospital; of these, 1 child recovered completely, 2 died, and autopsy on 1 showed "diffuse atrophy and gliosis of the brain"; 9 showed residual cerebral damage (5 had hemiplegia and 2 were virtually decerebrate); and 3 were under observation for too short a period for final assessment. Since the publication of this paper Byers (personal communication) has seen several more cases. Toomey (1949) reported 38 cases of convulsions following prophylactic pertussis vaccination which were collected after an appeal through American pædiatric journals and from a questionnaire sent to a large number of pædiatricians. In 25 of these there was sufficient detail for analysis; 2 had died, and the rest fully recovered. Globus and Kohn (1949) report 2 cases: one child was left with severe mental damage from which he is making a very slow recovery; the other declined progressively until death.

CASE-RECORD

A boy, born on June 6, 1946, was the second child of a twin delivery (uniovular). This was a first pregnancy, and delivery was spontaneous and rapid, the second stage lasting an hour. There was no evidence of compression of the skull, asphyxia, or distress. The child was normal in health and development until the age of 2 years 4 months, when he was admitted to hospital on Oct. 3, 1948, because of a generalised convulsion. This passed off rapidly but left him with a transient right hemiplegia, from which he fully recovered in five hours, and he was discharged from hospital next day. At the time of this illness three other children in the same house were suffering from mumps, and he was diagnosed as a case of mumps encephalitis. No investigations were carried out.

On Jan. 16, 1949, at the age of 2 years 7 months, the twins were immunised with combined diphtheria-pertussis antigens. One twin remained well, but the patient developed a generalised convulsion thirty-six hours later and was admitted to hospital.

On admission, on Jan. 18, he was comatose, and his temperature was subnormal but soon rose to 101·8°F. The coma deepened, and a few hours later there were further generalised convulsions. There was no neck rigidity or Kernig's sign. The pupils were small and equal, and there was a doubtful reaction to light. The fundi were normal. The conjunctival, abdominal, and cremasteric reflexes were absent, the deep reflexes were brisk, and there were bilateral extensor plantar responses. The heart and lungs were clinically normal. The cerebrospinal fluid (C.S.F.) contained 2 lymphocytes and 21 red cells per c.mm., protein 25 mg. per 100 ml. (globulin not increased); chlorides 720 mg. and sugar 18 mg. per 100 ml. (not collected in a fluoride tube). No organisms were found. The urine was acid and contained a trace of albumin, no sugar, some acetone, and chlorides 2 g. per litre. The convulsions were controlled with intramuscular sodium phenobarbitone gr. 1. Glucose in saline solution was given rectally.

Jan. 19: the child's clinical condition remained the same. His blood-sugar was 156 mg. and blood-urea 107 mg. per 100 ml.

Jan. 20: His temperature was normal. He was in a deep sleep and was roused with difficulty. He yawned frequently. The white-cell count was 11,000 per c.mm. (polymorphs 51%, lymphocytes 32%, monocytes 14%, eosinophils 1%). Lumbar puncture was repeated; the C.S.F. was clear, under a pressure of 25 cm. of H_2O, and contained 4 cells per c.mm. (2 red cells, 1 lymphocyte, and 1 polymorph), protein 30 mg. per 100 ml. (no increase of globulin), chlorides 720 mg. and sugar 95 mg. per 100 ml.; blood-urea 87 mg. and serum-calcium 2 mg. per 100 ml.; alkali reserve 50 vols CO_2%. Wassermann reaction negative.

Jan. 21: a right hemiplegia had developed and speech was lost completely.

Aug. 5 (age 3 years 2 months): radiograms of the skull showed no abnormality. A lumbar encephalogram showed much dilatation of the left lateral ventricle (figs. 1–4).

Oct. 12: electro-encephalogram showed diminished electrical activity of the left cerebral hemisphere (fig. 5).

State on discharge (Jan. 8, 1950, at the age of 3 years 7 months).—Some speech had returned, and he had a vocabulary of about ten words. He was progressing mentally, understood much of routine living, and was coöperative in the ward, though given to tantrums. He played with other children but with little sense of coöperation. The right arm and leg were still spastic, but the hemiplegia was diminishing, and he could walk without aid or support. A right homonymous hemianopia was present, but it was impossible to plot detailed visual fields.

DISCUSSION

Neurological complications are known to have followed the injection of pertussis antigen and combined diphtheria-pertussis antigens, but we have found no record of such complications following immunisation against diphtheria alone. It seems probable that the pertussis antigen was the cause of the sequelæ in the present case.

Among the suspected causes a specific toxin has been suggested. Bordet and Gengou (1906) suspected such a product of *Hæmophilus pertussis* in their original description of the organism, but it seems unlikely that such a toxin would survive in a properly aged vaccine, and few workers now support this theory.

In discussing constitutional predisposition, Byers and Moll (1948) emphasise the high incidence of a family history of neurological disorders in their cases and the fact that 12 of their 15 patients were males.

Toomey (1949), from the evidence he has collected, recommends that no child should be given pertussis vaccine if there is a family history of convulsions or if the child has a history of convulsions or other illness of the central nervous system, either present or past.

Ferraro (1944), from his own observations and from the published work, favours the view that an antigen-antibody reaction is the cause. The morbid anatomical findings of Werne and Garrow (1946) support this view. Brody (1947) states " it would seem likely that what is involved here is some sensitisation phenomenon " and emphasises the family history of allergy in his cases.

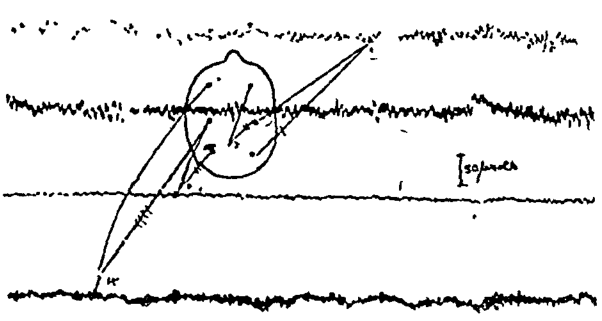

Fig. 5—Electro-encephalogram showing diminished electrical activity of left cerebral hemisphere.

He suggests that the mechanism resembles that of the neurological complications of erythroblastosis fœtalis, where there is a " plugging of the small cerebral vessels by agglutinated red cells . . . agglutinated as a result of a sensitisation phenomenon."

Many of the cases reported have occurred after a second or subsequent injection of the vaccine; in some there has been a history of previous convulsions. In the present case the convulsions followed the first inoculation (pertussis vaccination), but there had been a convulsion three months previously, when other children in the household had mumps.

Complications of pertussis vaccination are extremely rare, but the results are so serious that, until the prophylactic value of such vaccination is established beyond doubt, it may be desirable not to vaccinate a child in whom there is any suspicion of the stability of the central nervous system as shown by the personal or family history. If there is any untoward reaction to the first injection, no further injection should be given

SUMMARY

Severe neurological complications are described in a boy aged $2^1/_2$ years who developed convulsions thirty-six hours after the first injection of combined diphtheria-pertussis antigens.

Investigations made eight months later showed dilatation of the left lateral ventricle and diminished electrical activity of the left cerebral hemisphere.

A year later there was some recovery, but the patient still had a small vocabulary and was mentally retarded.

The pathogenesis is unknown, but in view of the reports of serious neurological complications it is suggested that pertussis vaccination should not be done if there is a history of convulsions in the child or the family; if there is any untoward reaction

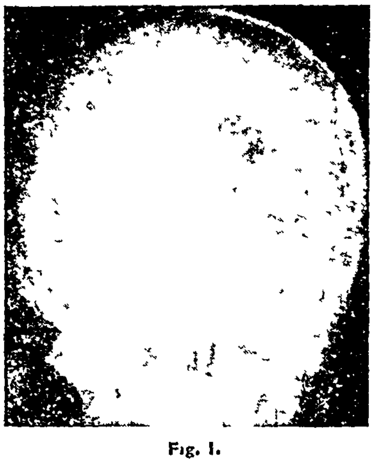

Fig. 1.

to the first injection further vaccination should be abandoned.

THE EFFECT OF REST IN BED ON PLASMA VOLUME

AS INDICATED BY HÆMOGLOBIN AND HÆMATOCRIT LEVELS

E. M. WIDDOWSON
D.Sc., Ph.D. Lond.

R. A. McCANCE
M.D., Ph.D. Camb., F.R.C.P., F.R.S.

From the Medical Research Council Department of Experimental Medicine, Cambridge

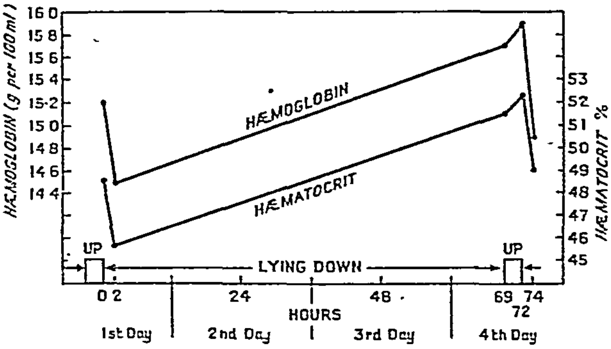
It has been known at least since Böhme's work in 1911 that a change from the vertical to the horizontal posture produces a fall in serum-proteins and hæmoglobin levels, and that a change from the horizontal to the vertical has the reverse effect. The alterations in serum-proteins and hæmoglobin occur within two hours, and it has generally been assumed that the values then reached are stable and do not change until the posture is altered once more. Widdowson and McCance (1950), however, found that the rise or fall in the circulating elements usually reached a maximum within two hours after the change of posture and the serum-protein, hæmoglobin, and hæmatocrit levels tended to return towards their original values in the next twelve hours or so. Further studies, with undernourished persons, showed that rest in bed led at first to a fall in protein, hæmoglobin, and hæmatocrit, but that after two hours these levels began to rise again, so that after three days they were no lower than before the persons went to bed. This increase in concentration could not be explained by loss of œdema fluid as measured by changes in body-weight.

Some experiments have therefore been made on well-nourished men and women, and the results are set out here. The previous experiments on undernourished persons are also mentioned.

MATERIAL AND METHODS

The subjects of the experiments were hospital patients whose complaints (hernias, indefinite gastro-intestinal troubles, &c.) were not likely to have any effect on the volume or composition of their blood. They were admitted to hospital at noon, and blood was at once withdrawn with a minimum of stasis. The subjects next undressed and lay quietly in bed for two hours, when a second sample of blood was collected with the same precautions as before. For the next sixty-seven hours the subjects remained in bed, with not more than two pillows, and on the morning of the third day after admission blood was again collected from some of the subjects, who then got up and stood and sat about in the wards till noon, when a fourth sample of blood was withdrawn. The subjects next lay on their beds again for two hours, when the fifth and last specimen of blood was taken. The other subjects were bled only once on the third day, and did not get up until the third and final sample of blood had been collected in the afternoon, at a time corresponding to the second specimen on the first day. A standard light midday meal was given on the test days.

For the determination of hæmoglobin and hæmatocrit, coagulation of the blood was prevented by adding to each 10 ml. of blood 0·02 g. of a mixture of two parts of potassium oxalate and three parts of ammonium oxalate. For the determination of serum-proteins the blood was collected without anticoagulant and was centrifuged within an hour of collection.



Variations in hæmoglobin and hæmatocrit levels induced by changes of posture and by three days' rest in bed.

Hæmatocrit was determined by centrifuging for 45 minutes at 3000 r.p.m.

Hæmoglobin was estimated by Gibson and Harrison's (1945) method. Both hæmoglobin and hæmatocrit were determined on the day the blood was collected.

Serum-proteins were estimated by precipitation with tungstic acid and subsequent digestion with sulphuric acid, copper selenide being used as catalyst. The nitrogen was determined by the micro-Kjeldahl technique (see Laboratory Techniques 1950).

CHANGES IN HÆMOGLOBIN, HÆMATOCRIT, AND SERUM-PROTEIN LEVELS IN 10 SUBJECTS AFTER LYING IN BED FOR TWO HOURS AND FOR THREE DAYS

Case no.	Sex	Hæmoglobin (g. per 100 ml.)			Hæmatocrit (%)			Serum-proteins (g. per 100 ml.)

RESULTS

The accompanying figure shows the average changes in the hæmoglobin and hæmatocrit levels of two subjects from whom blood was taken on five occasions, and the accompanying table the levels found in ten subjects who were bled when they were first admitted to hospital, after they had been recumbent for two hours, and after they had been in bed for three days. It will be seen from the figure that, after the well-known effect on the hæmoglobin and hæmatocrit levels of lying down for two hours, the values rose again over the next sixty-seven hours and were slightly higher on the morning of the fourth day than they had been on admission. They rose a little further when the subjects were up and about for a few hours in the morning, and after this period in the upright position they fell again when the subjects lay down. Though this fall was large and would certainly not have taken place had the subjects not got up, the final levels were still higher than those found after the subjects had been lying down for two hours on the day of admission. The net effect of three days' recumbency was therefore a rise in the hæmoglobin and hæmatocrit levels, which almost certainly was an expression of a fall in the volume of the plasma. These results are confirmed by the data in the table. It will be seen that the changes in serum-protein were less than those in the hæmoglobin and hæmatocrit, and not always in the same direction. It is suggested that this was due to some of the serum-proteins being taken up by the body cells or metabolised in the three days. At all events the changes in the serum-protein followed the changes in hæmoglobin and hæmatocrit much more closely over the shorter than over the longer periods of time.

Since rest in bed for three days produced alterations in the hæmatocrit and hæmoglobin levels comparable with those which follow a change from the horizontal to the vertical position, and since the rate of diuresis has often been shown to be reduced by this change (McCance 1950), 1200 ml. of water were given to nine of the patients after two hours in bed and again after three days in bed. When the water was given after two hours in bed the average volume excreted in the next five hours was 1268 ml., and when it was given after three days in bed the average volume was 1274 ml.; hence it may be concluded that, though three days in bed reduced the plasma volume it did not reduce the diuretic effect of water.

DISCUSSION

These observations are in entire accord with those made on undernourished men in Germany (Widdowson and McCance 1950), and it is evident that lying in bed for three days raises the hæmatocrit and hæmoglobin levels of well-nourished as well as of undernourished persons. The figure shows that the reasons for the changes are undoubtedly very complicated, for (1) protracted recumbency has exactly the opposite effect of short-term recumbency, and (2) *after* protracted recumbency a change to the vertical position for a few hours somehow alters the conditions so that a large and characteristic fall in concentration is observed when the person once more lies down.

It is generally assumed that the changes which take place in the two hours after a change of posture are the result of alterations in the volume of plasma, and possibly the increased concentrations which follow three days in bed are to be explained in a similar way by a fall in the plasma volume. If this is so, it remains to explain why the plasma, which appears to increase in volume during the first two hours after lying down, should then decrease in volume over the next three days. Posture and inactivity are probably both involved in these changes, and the secondary rise in concentration may be the result of protracted inactivity rather than of recumbency *per se*. This could be tested by making the persons take exercise in the recumbent position, but so far this has not been attempted. It seems desirable, however, to call attention to these results now, since the early effects of a change of posture on the constituents of the blood are at last becoming widely recognised, and their significance has been emphasised in assessing the true levels of hæmoglobin and serum-protein (Committee on Hæmoglobin Surveys 1945). It is evident that the protracted effects of recumbency may be equally important, and it cannot be assumed that lower values for hæmoglobin and serum-proteins will be found in blood taken when a person is recumbent than in blood taken from the same person when he is up and about. They may be quite as high in the recumbent as in the upright position if the person has been in bed for some days.

SUMMARY

When normal persons rested in bed for two hours their hæmoglobin, hæmatocrit, and serum-protein levels fell in the expected way; but if the rest was continued for three days the levels rose again to their original height.

Similar effects had previously been observed in undernourished persons.

It is suggested that this secondary rise in the concentration of the circulating elements may be the result of inactivity rather than recumbency.

The diuretic effect of 1200 ml. of water was not altered by three days in bed.

We are indebted to Dr. M. Shutter and Miss L. A. Thrussell for assistance in the collection of the samples of blood.

DEOXYCORTONE WITH ASCORBIC ACID IN MENTAL DISORDER

SOME CLINICAL AND LABORATORY FINDINGS

E. H. CRANSWICK
M.B. Sydney, D.P.M.
FORMERLY SENIOR REGISTRAR, RUNWELL HOSPITAL

T. C. HALL
M.F.R.
CHIEF LABORATORY TECHNICIAN AT THE HOSPITAL

Hench et al. (1949) found that treatment of rheumatoid arthritis with adrenocorticotropic hormone (A.C.T.H.) or 'Cortisone' often caused euphoria. Lewin and Wassén (1949) reported benefit in rheumatoid arthritis from giving deoxycortone and ascorbic acid together. We have tried Lewin and Wassén's technique in the following cases:

Schizophrenic psychoses	13	(2 of less than one years' duration.)
Depressive psychoses ..	17	(11 ,, ,, ,, ,, ,,
Manic psychoses ..	4	(3 ,, ,, ,, ,, ,,
Neuroses	3	
Rheumatoid arthritis ..	1	
Angioneurotic œdema	1	
Normal individuals ..	6	
Total	45	

The dose of deoxycortone varied from 2·5 to 10 mg., and after the first few trials it was always injected into the thigh muscles, three or four inches below the greater trochanter. The dose of ascorbic acid was always 1·0 g. intravenously.

CLINICAL RESULTS

Schizophrenic psychoses.—The 2 cases of less than a year's duration showed immediate benefit and have since maintained their improvement.

Before treatment both showed retardation of thought, and thought disorder at times amounting to "blocking." Both were lonely and asocial and suffered from derealisation-depersonalisation syndrome. Both showed anergia and emotional shallowness. After the combined injections, both showed rapid changes within thirty minutes; they became easy in social converse, showed more emotional depth, lost their anxious preoccupation with feelings of unreality, and became energetic and helpful in the ward. One of them, who had had auditory hallucinations and delusions of reference, developed full insight into these, and lost the feeling that time was "painfully fast" of which he had complained. He had 3 treatments and the other patient had 4; and, though the first treatment was followed by relapse in about a week, they have now remained well without further treatments in the past twelve weeks.

The single treatments given to the schizophrenics with a history of more than twelve months produced no changes that seemed significant.

Depressive psychoses.—In the 11 cases of less than a year's duration there were well-marked changes, whereas only 1 of the 6 chronic patients showed significant and lasting changes. The clinical changes noted were generally a feeling of well-being, amounting in some cases to euphoria, a decrease of retardation of thought, and an increase of activity and sociability. Delusions and hallucinations, which became much less prominent early in treatment, were not, however, lost, and tended to become prominent again as the patient relapsed. However, it was found that they were much less concealed during the phase of improvement, and it was possible to discuss them amicably with the patient. In general, a dose of 2·5 mg. deoxycortone was found more effective than one of 5 mg. A dose of 10 mg. was usually depressing: one patient complained bitterly of feeling worse than ever he had before. In the early stages of treatment, relapse usually took place within two days. As a rule, patients could be improved again by another treatment; but in 3 depressives with considerable amounts of neurotic reaction improvement failed to appear with later injections. In 1 case treatment failed on the fifth occasion, and in the other 2 on the third occasion. These failures occurred in spite of the patient's considerable confidence in the treatment.

In 1 chronic case the patient showed an initial striking improvement, into euphoria out of a state of misery and lethargy, an hour after the treatment. This improvement lasted twenty-four hours but was succeeded by a phase of more intense depression with the addition of negativistic and aggressive features. Further treatments failed to lift him out of this state, and recourse had to be made to electro-convulsion therapy (E.C.T.) before improvement set in again.

In 4 of the cases where treatment was persisted in on each relapse, there was a maintained remission; 1 patient has died from bronchopneumonia but the other 3 have had no treatment now for twelve weeks, without relapse. One of these is a man with chronic depression of twenty years' standing.

Our general impression from these cases and others now under treatment is that the patients do well if they have a history of less than twelve months, and if there is not a large neurotic element in their condition. A notable feature of the positive reactions has been their similarity to those following E.C.T. Of 12 patients who benefited previously or subsequently from E.C.T., 11 also showed benefit from deoxycortone with ascorbic acid. The 4 patients in this series who had E.C.T. without benefit did not improve on deoxycortone and ascorbic acid.

Manic psychoses.—2 patients with less than a year's history showed temporary great improvement following treatment. The improvement consisted in a feeling of calm ("loss of energy") and reduction of activity, aggressiveness, elation, and garrulousness. Improvement lasted one or two days. Both these cases benefited also from intensive E.C.T. One other case of less than a year's duration, who had previously responded temporarily to intensive E.C.T., did not show any response to deoxycortone and ascorbic acid. The fourth case, of longer standing, improved with neither method.

Neuroses.—Only 1 patient improved (still well after three months). The other 2 showed no change.

Somatic disturbances.—Deoxycortone with ascorbic acid was given to 2 members of the staff suffering from rheumatoid arthritis and angioneurotic œdema.

A woman of 51, who for three months had been under treatment at a general hospital for rheumatoid arthritis, had made very little improvement, and had considerable pain and stiffness in the left shoulder, elbow, and hand. There was wasting of the interossei in the left hand, and considerable swelling of the finger-joints. She displayed anxiety-tension and pessimism about her illness. At the time of her first injection she had a "streaming cold"; ten minutes later her colour was better, pain and stiffness rapidly began to leave the joints, mobility quickly returned, the rhinorrhœa disappeared, and she experienced considerable euphoria, amounting perhaps to elation. That night she was unable to sleep, being full of hopeful plans about the future. The first remission lasted eleven hours; treatment was resumed whenever relapse set in, and now, after 13 treatments, she has apparently completely recovered, having had no injections for the past five weeks. There has been no rise of blood-pressure during treatment, and weight has not increased. There appears to be a slight increase in the amount of hair on the legs, but no other changes. Emotionally she is now alert, confident, and optimistic.

The second patient was suffering from angioneurotic œdema involving face, scalp, ears (with watery otorrhœa and partial deafness), and scrotum. He was anxious, irritable and preoccupied with his condition. Half an hour after the first treatment all œdema had vanished, and he was quite elated. This elation was noted particularly by his family when he arrived home that evening. It prevented him from sleeping on the first night. Remission lasted from one to three days, and after 3 treatments he has remained well for three months.

Normal individuals.—Effects on normal people were either nil, or only subjective. One of us (E. H. C.)

TABLE I—CLINICAL RESULTS WITH DEOXYCORTONE AND ASCORBIC ACID

Condition	No. of cases	Under 12 months' duration			Over 12 months' duration			Ratio of response to E.C.T.*	No. in remission following this treatment alone
		No.	+++ reaction	Other reactions	No.	+++ reaction	Other reactions		
Schizophrenia	13	2	2	—	11	0	1 ++ 1 +	0/2†	2
Depression	17	11	10	1 Nil‡	6	2	4 Nil	11/12	4 §
Mania	4	3	2	1 Nil	1	0	1 Nil	2/3†	—
Neuroses	3	0	—	—	3	1	2 Nil	—	1
Rheumatoid arthritis	1	1	1	—	—	—	—	—	1
Angioneurotic œdema	1	1	1	—	—	—	—	—	1
Normal	6	—	—	2 +	—	—	—	—	—

+ = Subjective feelings of relief without definite objective changes.

++ = Some subjective and objective changes not lasting twenty-four hours.

+++ = Marked subjective and objective changes lasting more than twenty-four hours.

++++ = Changes so great as to reverse the clinical picture.

Nil = No change either subjective or objective.

* Ratio of response to E.C.T. means the number of patients actually benefiting from deoxycortone with ascorbic acid—i.e., Deox.-Asc., who also benefited from E.C.T., shown as a ratio of the number of patients benefiting from E.C.T. who also were given deoxycortone and ascorbic acid.

† Benefit from E.C.T. was only obtained from intensive E.C.T.

‡ This man was considerably improved after twenty-four hours, but it is impossible to be sure whether it was due to deoxycortone and ascorbic acid.

§ One patient died from bronchopneumonia four weeks after last treatment.

experienced no notable change with the usual dosage. With a dosage of 10 mg. deoxycortone in the combined treatment, after half an hour there was a feeling of irritability, anxiety, fatigue, and precordial oppression. The diastolic pressure rose from 90 to 120 mm. The symptoms abated in four hours. In the third experiment 2·5 mg. was used; after fifteen minutes there were feelings of euphoria coupled with tranquillity, whilst a colleague reported that there seemed to be a reduction in the psychomotor activities. Another normal subject noted similar changes after the standard treatment. No changes were noted in the other 4 normal individuals.

Side-effects.—All the early cases in this series had frequent observations of the blood-pressure and pulse, after the injections. Only when the dosage of deoxycortone exceeded 5 mg. was any rise in the blood-pressure noted, and most of the depressives showed a slight fall. None of the patients showed any notable gain in weight. No investigations of blood sodium or chloride were made.

E.C.T.—Of the patients who reacted positively to deoxycortone with ascorbic acid, 2 were given E.C.T. during this investigation, to compare the clinical and biochemical changes. One was a case of mania and one of depression, and their improvement after E.C.T. was *rather greater than their improvement after deoxycortone* and ascorbic acid.

Summary.—The clinical results are set out in table I.

LABORATORY INVESTIGATIONS

To test whether the changes following treatment were due to the elaboration of a cortisone-like substance, a number of patients, both positive and negative reactors to the treatment, were investigated for changes in the eosinophil count, and the urinary uric-acid/creatinine ratio. These investigations were carried out under basal conditions with standard biochemical techniques, and the results are shown in table II.

Blood and urine specimens were taken from the patient at the time of the injection, two hours after the injection, and then four hours after. Hæmatocrit estimations, were carried out on all blood specimens. Only one (no. 9), showed any change, 54 in the basal value and 43 and 42 in the next two values. The others were of normal value and remained the same throughout.

DISCUSSION

It will be seen that in all but 1 case the +++ reaction was associated with a fall of at least 40% in the eosinophils. In the case (no. 9) where the fall was lower (33%) there was a change in the hæmatocrit value and a 173% plus change in the urinary uric-acid/creatinine ratio. When the reaction was below +++ the maximum fall of the eosinophils was 26%. With a +++ reaction all cases showed a rise of urinary uric-acid/creatinine ratio of at least 75%—except case 7, in which the eosinophil fall was 61%. When the reaction was *below* +++ the maximum rise in the ratio was 56%, except in case 3 where *it* was 104%; but the corresponding eosinophil fall was only 26%.

These findings strongly suggest that a cortisone-like substance is formed in the body by the interaction of deoxycortone and ascorbic acid, because only the 11-17 oxysteroids have *this joint action of reducing* the eosinophils and increasing the urinary uric-acid/creatinine ratio. American workers have suggested that E.C.T. acts through adrenal stimulation via A.C.T.H. (Altschule et al. 1949a and b). In our cases 10 and 11 the effects of E.C.T. were rather stronger than those of deoxycortone with ascorbic acid, which supports the above hypothesis. It *is interesting to note* that ascorbic acid alone, given in case 10 three days after the completion of a course of intensive E.C.T. (2 grand-mals a day for three days), produced a change just as great as any recorded with deoxycortone and ascorbic acid together. Perhaps the injected ascorbic acid replaced the *ascorbic* acid which had been metabolised during the intensive stimulation of the adrenal cortex by E.C.T. This would serve to stimulate adrenocortical activity again.

Le Vay and Loxton (1950) have shown in experiments *that deoxycortone and cortisone may act* peripherally. However, the effects we observed on the eosinophils and on uric-acid excretion, suggest in addition a central action—e.g., on *the adrenal cortex itself.*

Selye (1947) has pointed out the antagonism between deoxycortone and cortisone; and it may well be that the varying effects we have reported are due to antagonism between the cortisone-like substance formed and the deoxycortone left unchanged. Thus, injected ascorbic acid may convert some of the endogenous desoxocortisone (Selye 1950) into cortisone-like substance [see Brownlee (1950) on beneficial effects of ascorbic acid alone in normal animals], or, alternatively, injected deoxycortone may react with endogenous ascorbic acid to produce the cortisone-like substance.

Further work may show that it is possible to regard some psychotic states as an "exhaustion stage" in Selye's "alarm—adaptation syndrome" (Selye 1946) with the typical syndrome reduction of adrenocortical activity. Important American work already has demonstrated that, in chronic schizophrenics, there is often "adrenal unresponsiveness" both to A.C.T.H. and to stress (Pincus et al. 1949).

In conclusion, we wish to emphasise that the primary aim of these investigations was not formulation of a new therapy, but rather to note any changes that might follow administration of these substances. It appears to us now that there is justification for proceeding to cautious systematic trials of varying therapeutic régimes along these lines.

SUMMARY

1. Deoxycortone with ascorbic acid, given as suggested by Lewin and Wassén, has been tried in 45 persons of whom 37 had mental disorder, 2 had somatic disorder, and 6 were normal.

2. In general, mental cases with histories under twelve months showed euphoric reactions, whose effects were beneficial and in some cases led to a good remission.

3. The fall in eosinophil counts, and the changes in the urinary uric-acid/creatinine ratio, associated with response to this treatment, suggest that it causes, in the body, the production of a cortisone-like substance.

4. There has been a close correlation between the reaction of patients to this form of treatment and to electro-convulsive therapy.

We wish to thank Dr. H. Weil-Malherbe, director of research at Runwell Hospital, for advice and help in the carrying out of this investigation, and Mrs. P. R. Kent for help in the presentation of the results and setting out of the paper.

ROYAL SOCIETY OF MEDICINE

The Newer Antibiotics

THE section of experimental medicine met on March 14, with Prof. G. W. PICKERING in the chair.

Prof. ROBERT CRUICKSHANK traced the development of modern chemotherapy through the work of Ehrlich, Domagk, Fleming, Florey, Dubos, and Waksman. The bacteriologist had played a great part in this development and he also played a great part in the daily use of these new remedies. He must identify the organism responsible for the illness, test its sensitivity, and advise on the most suitable chemotherapeutic agent. Professor Cruickshank reviewed some of the antibiotics from four aspects:

Therapeutic effectiveness.—The relative sensitivity of the different organisms to the different drugs in vitro was no sure guide to their therapeutic efficiency in vivo. Thus in vitro polymyxin was very active in preventing the growth of *Salmonella* organisms, but it had proved disappointing in the treatment of typhoid; on the other hand *Pseudomonas pyocyanea* often responded well to polymyxin when applied locally.

Pneumonia might be due to numerous different organisms, which differed in their response to the main antibiotics; for rational therapy the organism should be identified. In some cases the organism, when isolated, might appear in the laboratory to be resistant to penicillin (or to some other antibiotic), but this did not always mean that a therapeutic response was unobtainable; when the dose of penicillin was increased from 100,000 to 4 million units per day, a rapid clinical improvement often ensued. Moreover, sometimes the pathogenic organisms were located in a relatively inaccessible site, and, to reach such a site, it might be necessary to drench the tissues with antibiotic.

To evaluate the true value of any new drug, carefully controlled trials were necessary. Good examples of such trials had been those of streptomycin organised by the Medical Research Council. The Council was now arranging trials on whooping-cough, infantile gastro-enteritis, pneumonia of children and of adults, and other infections.

Toxicity.—The drug might cause local irritation of the stomach—for example, large doses of 'Aureomycin' might cause nausea and vomiting. In this connection, it might be questioned whether starting treatment with a loading dose was really desirable, particularly in chronic infections, such as brucellosis.

There might be allergic reactions to the drug itself or to bacterial products suddenly released; hitherto this had not happened much with either chloramphenicol or aureomycin. There might also be definite toxic effects on the tissues. Thus streptomycin tended to damage the labyrinth and auditory apparatus; and it had been suggested that 'Chloromycetin' tended to cause abnormal fatigue in the muscles and ophthalmoplegia. The antibiotic might eliminate valuable bacteria from the intestine or respiratory tract, leading to the loss of valuable vitamins—e.g., vitamins B or K—or to the establishment of undesirable secondary organisms.

Finally, drug resistance might develop, as in tuberculosis treated with streptomycin: it had not yet been seen in typhoid treated with chloramphenicol.

Ease of administration.—Chloramphenicol and aureomycin could be given by mouth whereas penicillin was usually given by injection. But penicillin could be given by mouth if desired, using large doses (e.g., 1 g.) administered on an empty stomach. This was particularly effective for young children; and even with adults enough was usually absorbed to produce a good response.

Cost.—Weight for weight penicillin was cheaper than chloramphenicol and aureomycin; but these could often be administered to patients at home, whereas a course of injections with penicillin required admission to hospital. In this light chloromycetin and aureomycin were often less expensive than penicillin.

Among the disadvantages of the newer antibiotics must be reckoned the bitter taste; but in children under 1 year the taste-buds were not fully developed and so they did not object to the taste, and children older than 4 years could usually swallow capsules. Another disadvantage of these drugs was that their action was bacteriostatic rather than bactericidal, as was proved by the tendency of some infections to relapse after treatment had ceased; perhaps it might be possible to reinforce their action with antiserum.

The value of these drugs for meningitis, especially when due to Pfeiffer's bacillus, was still uncertain. Unfortunately nothing had yet been found which would sterilise carriers of typhoid or similar organisms. Urinary infections due to *Proteus* or *Ps. pyocyanea* were still difficult to treat. Apparently psittacosis and trachoma responded well to chloramphenicol and aureomycin, and it was reported that herpes zoster and herpes simplex also responded. But these substances had no effect in smallpox or chickenpox. There was still much scope for further study of these remedies, and for further new ones with a different range of action.

Dr. R. LEWTHWAITE described the work on chloramphenicol which had been done in Malaya by the American team. This work began with Prof. J. E. Smadel's discovery that rickettsial infections in fertile eggs could be cured by this compound. With the cordial welcome of the Malayan government he went to Malaya in 1948, taking with him one pound of chloramphenicol, which represented almost the total world supply at that time. Scrub-typhus was a virulent infection spread by a mite (*Trombicula dehliensis*) living in the grass; and the disease had caused serious casualties among our troops during the Burma campaign. The mortality was usually about 15%. The response of scrub-typhus to chloramphenicol was dramatic; within forty-eight hours of the beginning of oral treatment the clinical condition improved greatly.

Experiments were made to see if chloramphenicol would have prophylactic action, the drug being given while volunteers were exposed to infection. As long as the drug was being given, scrub-typhus did not develop; but about 10 days after the end of treatment almost all the volunteers fell ill with the disease. Further work showed that the disease could be prevented if chloramphenicol were given once weekly, continuing for several weeks after exposure to infection. During this time symptoms of incipient scrub-typhus might appear, but they were cut short by the next dose. The drug did not kill the rickettsiæ, but it prevented their multiplying until at last the body could deal with them itself.

Typhoid fever also responded to chloramphenicol (a discovery which had since been amply confirmed elsewhere). If the treatment were continued for less than 9 days, relapse often occurred; and so Smadel recommended that treatment should continue for at least 12 days. Unfortunately chloramphenicol did not prevent the patient becoming a carrier; nor did it free him from the organism when he had become a carrier.

Among other infections, gonorrhœa was readily cured by chloramphenicol, and patients might lose all symptoms within 1–2 days of taking a single oral dose. More recently Dr. A. J. Boase had reported from Uganda that trachoma responded very well too aureomycin, given by instillation; apparently it also responded well to chloramphenicol. If these findings were confirmed (as was expected) this would be a development of the greatest importance, since trachoma was very common and very troublesome in most of the warmer parts of the world.

Prof. J. M. SMELLIE spoke about the treatment of infantile gastro-enteritis—a condition which had been the subject of much research for many years and which still caused about an eighth of the deaths in the first year of life. Possibly a virus was concerned in the ætiology. At present, treatment was mainly symptomatic, with an attempt to correct dehydration and electrolytic disturbances. Hopes had been raised by sulphonamides, penicillin, and streptomycin; but each in turn had failed. During the past eight months, chloramphenicol had been used to treat 27 children (mostly under 6 months old) at the Children's Hospital, Birmingham; of these, 17 were critically ill at the start, and had to be given intravenous alimentation. Each was given a minimum of 2½ oz. of fluid per lb. body-weight per day. The dose of chloromycetin was 75 mg. per lb. per day in divided doses every 3–4 hours, the dose being mixed with a little syrup and given by a teaspoon. Despite the bitter taste, there was no difficulty in persuading the children to swallow it. Treatment usually lasted 10–12 days. In all but one of the cases (a hopeless one from the start) the clinical condition improved appreciably within 1–2 days of the administration of chloramphenicol. Diarrhœa abated, pyrexia (when present) ceased, and the toxæmia diminished. In a few of the patients a superimposed parenteral infection was also present, but this also responded well to the chloramphenicol. Untoward reactions to the drug were few. In some cases the infants suffered from sore buttocks, but this was probably not due to the drug. In 2 a cutaneous eruption was seen—one a generalised papular type of urticaria, and the other an allergic dermatitis of the buttocks and groins.

The assessment of any treatment of infantile gastro-enteritis was very difficult since the disease itself varied greatly in severity and intensity. But, even by the most cautious estimate, the results obtained with chloromycetin were more promising than any which had been achieved with other chemotherapeutic and antibiotic remedies.

Dr. E. N. ALLOTT said that 21 cases of typhoid fever had been treated with chloramphenicol at Lewisham Hospital. Some were given 20 g. during 48 hours. Others received the course recommended by Smadel—i.e., a loading dose of 4 g. followed by 1·5 g. twice daily until symptoms stopped, and then a maintenance dose for a total of 12–14 days. The relapse-rate was equally high whichever course was followed, but all the relapses responded well to further treatment. Relapses tended to occur 11–15 days after the end of treatment; this was also the incubation period. He suggested that short courses should be given and repeated at the time when a relapse might be expected—i.e., after 10–11 days.

Chloramphenicol in Typhoid Fever

At the meeting of the section of epidemiology on March 17, the discussion was opened by Dr. W. H. BRADLEY, president of the section, who was in the chair.

Dr. Bradley recalled that it was Smadel's success with chloramphenicol in typhoid fever that led the Ministry of Health to ask Parke, Davis & Co. to import some of the drug for a trial in this country. An outbreak at Crowthorne, Berkshire, provided the first opportunity, and a preliminary note on the early findings was published in THE LANCET a year ago (1949, i, 869). Shortage of the drug and the condition of some of the patients led to changes in the plan for this trial, and eventually chloramphenicol had to be used in "control patients" to save life. The outbreak was due to *Salmonella typhi* of phage-type E.1. In his preliminary communication Dr. Bradley stated that after resolution of temperature when chloramphenicol had been given for 8 days, recovery appeared complete. This proved not to be so, for subsequently 6 of the 12 treated patients, and also 6 of the 12 untreated cases relapsed. In the treatment of these relapses the effect of chloramphenicol was again dramatic and consistent. On the advice of Dr. R. Lewthwaite, treatment was continued for several days over the eight originally proposed by Woodward; this seemed to prevent relapses, but in Smadel's more recent experience treatment for eighteen days was guarantee against relapse. Woodward had suggested that relapses were particularly common in patients treated with this drug, but Dr. Bradley was not satisfied that this was so. There might be better ways of preventing relapses than merely continuing the treatment longer. A clearer picture of the natural history of relapses was needed; Dr. Bradley's impression was that they occurred with a fairly regular periodicity, and it might be wise to give a short second course at the time when relapse might be expected. Alternatively, more intensive treatment early in the disease, or (improbably) a boosting dose of vaccine or a course of serum might reduce the incidence of relapses. In the treatment of the 70-odd moderately severe cases in the outbreak originating from the R.M.S. *Mooltan*, Dr. Bradley suggested that Dr. Armstrong should use massive doses comparable with those which Gray gave in whooping-cough. The results seemed no better than with the original Woodward dosage—in fact, there were little "flicks" in the temperature charts not observed with the smaller dosage; and signs of muscle weakness (blurred vision, for example) appeared, confirming Gray's observations. It was, however, learnt that patients with severe typhoid could be given 20 g. in two days without undue risk.

There was no doubt about the value of chloramphenicol in typhoid. The disappointing feature was its failure to prevent the development of the "chronic carrier" state. Thus in one case, although two courses of chloramphenicol had been given, the stools were still positive on discharge from hospital on the 83rd day. So far the the drug had failed, even in massive doses, to clear chronic carriers. However, hope should not be given up of applying chloramphenicol, "using some cunning and at present unsuspected technique," to the prevention of the carrier state and the cure of the carrier.

Dr. R. A. GOOD described the results in the Crowthorne cases treated at Winchester. The 5 men and 8 women admitted were divided, by the alternate case method, into 6 treated with chloramphenicol and 7 controls: later 2 of the controls were given the drug as a life-saving measure. The temperature fell in 72 hours in all the treated cases, but an equal number relapsed in the two groups; the relapses occurred about the 35th day in the treated cases and about the 25th in the untreated. One of the treated cases, a woman of 24, who had had T.A.B. vaccine during the war, developed a chronic carrier state.

Dr. A. L. K. RANKIN described 18 cases admitted between May, 1949, and January, 1950; 10 of them were from Crowthorne. Altogether, 13 primary or relapsed cases were given chloramphenicol: one of these patients, a man of 77, died. No toxic or side effects of the drug were observed, and no increased resistance to chloramphenicol was demonstrable in the organisms. The prognosis of typhoid, Dr. Rankin recalled, was progressively less favourable in elderly patients. In this series a third of the patients were over 58, and apart from the one man admitted in a hopeless condition, all recovered. He felt that chloramphenicol was responsible for this result in at least some of the cases. Given in adequate doses, chloramphenicol was most effective. It also eased the strain on the nursing staff, although the success of any treatment of typhoid still largely depended on the efficiency and enthusiasm of the nurses.

Dr. R. LEWTHWAITE described 2 relapses among his early patients in Malaya, and referred to Woodward's "interrupted" method of treatment, as described by Smadel, in which the drug was given for five days, then treatment was stopped for five days, and then the original course was repeated. Even after eighteen days' treatment, relapses would still happen occasionally; when the morbid anatomy of the disease was considered, this was not surprising. Dr. Lewthwaite was pleased that the synthetic drug worked as well as the one made by fermentation.

Dr. STANLEY WHITE added that chloramphenicol was the only antibiotic which it was possible to synthesise on a practical basis. Smadel considered that its action was bacteriostatic, not bactericidal, but some workers would not accept this statement in its entirety. Assuming that Smadel was right, it followed that unless the drug was given in sufficient amount over a sufficient time, there were going to be relapses. The method now advocated was to give a total of 30 g. over not less than a fortnight. When a relapse occurred, it responded even more dramatically than the primary attack to chloramphenicol therapy, presumably because the defence mechanism was already in action. In Smadel's opinion there was no reason to believe that the carrier state would develop more often in patients who had had chloramphenicol than in those who had not. Dr. White advocated large doses in paratyphoid. Chloramphenicol interfered with carbohydrate metabolism, and affected vitamins B_1 and B_2 and nicotinic acid: vitamin K might also be involved. A possible explanation was that chloramphenicol not only sterilised the upper respiratory tract but killed the organisms which synthesised the B group; therefore one should give large doses of vitamin-B complex when treating any infection with chloramphenicol.

Dr. C. F. L. HILL described the results in 21 cases from the *Mooltan*, 10 being given a short course of chloramphenicol (an initial dose of 4 g. followed by eight-hourly or six-hourly doses of 2 g.), and 11 a longer course (an initial dose of 4 g. and then 20–35 g. over nine to eighteen days). There was no significant difference in the relapse-rate of the two groups, relapse occurring in about half of the cases. It might be possible to suppress a relapse by giving a further course of the drug ten days after the completion of the first course. He was not convinced of the efficacy of the two-day course.

Dr. C. K. MCDONALD, discussing blood-cultures and stool-cultures, said it would be helpful if there could be some standard method of assaying the drug in the blood. There did not seem to be any chloramphenicol-resistant strains of *S. typhi*.

Dr. D. C. LIDDLE spoke of the outbreak of typhoid at Salford in October, 1949. Of 20 patients admitted to hospital, 17 were treated with chloramphenicol. Two of them died—a man of 58 whose death was primarily due to arterial thrombosis, and a man of 40 who was given a five-day course. His temperature settled and he seemed well, but a fortnight before he died he complained, once only, of a pain in the calf, and he died of pulmonary embolism. In the first case no organisms were found in the bile but they were present in the spleen, bone-marrow, and liver. In the other the organisms were present in the bile, spleen, and lungs, but not in the liver. The patient who had organisms in his bile had been excreting them in his fæces: the one who had none in his fæces was found to have none in his bile. Relapses occurred in 5 inadequately treated cases. All the cases who developed complications were those who had been partially treated. Some patients were given a full course, and he had formed the impression that a thorough course, lasting over fifteen days, was necessary to prevent complications. Whenever chloramphenicol was given, a patient should have his blood-sedimentation rate estimated before being allowed up. The patients responded so rapidly to treatment that they tended to become euphoric about the 3rd or 4th day, but they should not get up before they were fit to do so.

Dr. STANLEY BANKS, discussing the question of chloramphenicol's bacteriostatic or bactericidal action, said that though Smadel considered it to be the former, there was some clinical evidence of the latter. The French had noted the psychiatric reaction which might be thought to be in the nature of a Herxheimer reaction, due to rapid killing of the organisms. He mentioned a case of paratyphoid B in a child in which chloramphenicol appeared to have no effect, though the French seemed to have found that it had the same effect as in typhoid. The interference with vitamins B and K in the gut was a point in favour of intermittency of treatment.

Dr. IAN TAYLOR produced some figures in relation to relapse-rates. In the Croydon outbreak of 341 cases, the relapse-rate was 20% and the case-mortality 15%. At Bournemouth 495 cases produced 38 deaths and "a few" relapses. It did seem that the consistent finding and it was reported that herpes zoster and herpes simplex also responded. But these substances had no effect in smallpox or chickenpox. There was still much scope for further study of these remedies, and for further new ones with a different range of action.

Dr. R. LEWTHWAITE described the work on chloramphenicol which had been done in Malaya by the American team. This work began with Prof. J. E. Smadel's discovery that rickettsial infections in fertile eggs could be cured by this compound. With the cordial welcome of the Malayan government he went to Malaya in 1948, taking with him one pound of chloramphenicol, which represented almost the total world supply at that time. Scrub-typhus was a virulent infection spread by a mite (*Trombicula dehliensis*) living in the grass; and the disease had caused serious casualties among our troops during the Burma campaign. The mortality was usually about 15%. The response of scrub-typhus to chloramphenicol was dramatic; within forty-eight hours of the beginning of oral treatment the clinical condition improved greatly.

Experiments were made to see if chloramphenicol would have prophylactic action, the drug being given while volunteers were exposed to infection. As long as the drug was being given, scrub-typhus did not develop; but about 10 days after the end of treatment almost all the volunteers fell ill with the disease. Further work showed that the disease could be prevented if chloramphenicol were given once weekly, continuing for several weeks after exposure to infection. During this time symptoms of incipient scrub-typhus might appear, but they were cut short by the next dose. The drug did not kill the rickettsiæ, but it prevented their multiplying until at last the body could deal with them itself.

Typhoid fever also responded to chloramphenicol (a discovery which had since been amply confirmed elsewhere). If the treatment were continued for less than 9 days, relapse often occurred; and so Smadel recommended that treatment should continue for at least 12 days. Unfortunately chloramphenicol did not prevent the patient becoming a carrier; nor did it free him from the organism when he had become a carrier.

Among other infections, gonorrhœa was readily cured by chloramphenicol, and patients might lose all symptoms within 1–2 days of taking a single oral dose. More recently Dr. A. J. Boase had reported from Uganda that trachoma responded very well too aureomycin, given by instillation; apparently it also responded well to chloramphenicol. If these findings were confirmed (as was expected) this would be a development of the greatest importance, since trachoma was very common and very troublesome in most of the warmer parts of the world.

Prof. J. M. SMELLIE spoke about the treatment of infantile gastro-enteritis—a condition which had been the subject of much research for many years and which still caused about an eighth of the deaths in the first year of life. Possibly a virus was concerned in the ætiology. At present, treatment was mainly symptomatic, with an attempt to correct dehydration and electrolytic disturbances. Hopes had been raised by sulphonamides, penicillin, and streptomycin; but each in turn had failed. During the past eight months, chloramphenicol had been used to treat 27 children (mostly under 6 months old) at the Children's Hospital, Birmingham; of these, 17 were critically ill at the start, and had to be given intravenous alimentation. Each was given a minimum of 2½ oz. of fluid per lb. body-weight per day. The dose of chloromycetin was 75 mg. per lb. per day in divided doses every 3–4 hours, the dose being mixed with a little syrup and given by a teaspoon. Despite the bitter taste, there was no difficulty in persuading the children to swallow it. Treatment usually lasted 10–12 days. In all but one of the cases (a hopeless one from the start) the clinical condition improved appreciably within 1–2 days of the administration of chloramphenicol. Diarrhœa abated, pyrexia (when present) ceased, and the toxæmia diminished. In a few of the patients a superimposed parenteral infection was also present, but this also responded well to the chloramphenicol. Untoward reactions to the drug were few. In some cases the infants suffered from sore buttocks, but this was probably not due to the drug. In 2 a cutaneous eruption was seen—one a generalised papular type of urticaria, and the other an allergic dermatitis of the buttocks and groins.

The assessment of any treatment of infantile gastro-enteritis was very difficult since the disease itself varied greatly in severity and intensity. But, even by the most cautious estimate, the results obtained with chloromycetin were more promising than any which had been achieved with other chemotherapeutic and antibiotic remedies.

Dr. E. N. ALLOTT said that 21 cases of typhoid fever had been treated with chloramphenicol at Lewisham Hospital. Some were given 20 g. during 48 hours. Others received the course recommended by Smadel—i.e., a loading dose of 4 g. followed by 1·5 g. twice daily until symptoms stopped, and then a maintenance dose for a total of 12–14 days. The relapse-rate was equally high whichever course was followed, but all the relapses responded well to further treatment. Relapses tended to occur 11–15 days after the end of treatment; this was also the incubation period. He suggested that short courses should be given and repeated at the time when a relapse might be expected—i.e., after 10–11 days.

Chloramphenicol in Typhoid Fever

At the meeting of the section of epidemiology on March 17, the discussion was opened by Dr. W. H. BRADLEY, president of the section, who was in the chair.

Dr. Bradley recalled that it was Smadel's success with chloramphenicol in typhoid fever that led the Ministry of Health to ask Parke, Davis & Co. to import some of the drug for a trial in this country. An outbreak at Crowthorne, Berkshire, provided the first opportunity, and a preliminary note on the early findings was published in THE LANCET a year ago (1949, i, 869). Shortage of the drug and the condition of some of the patients led to changes in the plan for this trial, and eventually chloramphenicol had to be used in "control patients" to save life. The outbreak was due to *Salmonella typhi* of phage-type E.1. In his preliminary communication Dr. Bradley stated that after resolution of temperature when chloramphenicol had been given for 8 days, recovery appeared complete. This proved not to be so, for subsequently 6 of the 12 treated patients, and also 6 of the 12 untreated cases relapsed. In the treatment of these relapses the effect of chloramphenicol was again dramatic and consistent. On the advice of Dr. R. Lewthwaite, treatment was continued for several days over the eight originally proposed by Woodward; this seemed to prevent relapses, but in Smadel's more recent experience treatment for eighteen days was guarantee against relapse. Woodward had suggested that relapses were particularly common in patients treated with this drug, but Dr. Bradley was not satisfied that this was so. There might be better ways of preventing relapses than merely continuing the treatment longer. A clearer picture of the natural history of relapses was needed; Dr. Bradley's impression was that they occurred with a fairly regular periodicity, and it might be wise to give a short second course at the time when relapse might be expected. Alternatively, more intensive treatment early in the disease, or (improbably) a boosting dose of vaccine or a course of serum might reduce the incidence of relapses. In the treatment of

The Collings Report

Dr. COLLINGS, whose report on the present state of English general practice we publish this week, is a young Australian who had previously studied medical work in his own country, in New Zealand, in Canada, and in the United States. His one-man reconnaissance of a territory so often surveyed by its inhabitants may seem unnecessary or even impudent; but a single scout sometimes learns more than a party, and the chief features of a countryside are often picked out most easily by a stranger. COLLINGS had the advantage of knowing other comparable countrysides, but he has looked on England with fresh eyes. His report is quite unlike the compilation of a committee; if it lacks the kind of wisdom attained by compromises and qualifying clauses, it has the merit of saying plainly what he saw and what he thinks. His capabilities as observer and commentator are obvious: indeed in presenting such a report he presents his own credentials.

On what he saw, he concludes that "the over-all state of general practice is bad and still deteriorating." In industrial areas, where the demand for good medical care is greatest and most urgent, practice "has reached a point where, despite the efforts of the most conscientious individual doctors, it is at the best a very unsatisfactory medical service and at the worst a positive source of public danger." Conditions of work are sometimes such as to change a good doctor to a bad doctor within a short time, thus neutralising much of the sound teaching of the medical schools. Paradoxically, practice is worst in close proximity to large hospital centres and "improves in both scope and quality almost in proportion to the distance away from those centres." But even in the country districts present-day practice "remains an anachronism, though one which has retained many of the virtues of the past." The National Health Service Act has increased the load on general practice and at some points has caused serious strain; but "many of the shortcomings attributed directly to the Act are the result of basic weaknesses," and "blame rests on the service only in so far as it has failed to provide the means of reinforcing general practice, so that it can take the new load."

To anyone accustomed to think of the English general practitioner, and English general practice, as the best in the world, these blunt statements from an outside observer come as a surprise; and they raise two questions: (1) were the 55 English practices examined a fair and representative sample, as COLLINGS believes, and (2) has he assessed them accurately? Those interested will need to read the report before reaching an opinion. Statistically, of course, the 55 practices are a small sample, and they were not selected at random; hence it is quite possible that an unduly large proportion of unsatisfactory ones were seen. More important, however, is the question whether the estimates formed after a period of one to four days "sitting in on" the practice were sound. Doctors who identify their own practices, and the far larger number to whom the criticisms might equally well apply, will often feel that a partial view has been taken; that the best features of their work have been ignored while insignificant details have been emphasised; that the essentials of medical care have little to do with filing-cabinets and examining-couches; and that wrong impressions can easily be gained from a few hours' observation under somewhat artificial conditions. They may say, with some reason, that for COLLINGS, as an Australian, the ideal general practitioner seems to be a man equipped and ready to deal with anything five hundred miles from anywhere; whereas in England, with its hospitals and specialists, the G.P.'s rôle is different. But those who read his report carefully will find him expressing as much admiration as disapproval. They will note, too, that the criticism is professional, not personal, and is directed almost always against the system and not the people working it. Some of the practices he criticises most strongly are run by the doctors whom, as men, he most respects. Of the industrial areas he writes "it is neither my purpose nor my desire to defame the overworked and often conscientious doctor who has to suffer the indignities of this way of working." If some feel that the picture is painted in colours too dark, or with contrasts too sharp, let it be remembered that the artist's aim is neither to praise nor to blame, but to display these indignities that they may be removed. They may or may not be as widespread as he supposes, but the fact that they exist at all calls for determined action.

"I regard the errors," COLLINGS says, "as merely symptoms of the chronic illness of general practice today"; and he reviews the causes of this illness. For several decades general practice has adapted itself to the growth and development of hospital, specialist, and other medical services; but "this process has resulted in the decline rather than the progressive evolution of general practice, and in wide departure from both the idea and the ideal of family doctoring." The scope and interest of the practitioner's work has steadily contracted. The local-authority services undertake much that was once in his charge: though supposedly complementary to the practitioner, they are in fact substitutes for him. The hospitals, in excluding him from their staffs and removing patients from his ken, have gone far to isolate him professionally and depress his standards. More and more the specialist invades general practice, the latest invaders being the pædiatrician ("nothing seems to be too menial for him") and the geriatrician, both of whom seek responsibility for whole age-groups of society. The current tendency, as COLLINGS sees it, is always to compensate for deficiencies in general practice, by extending the activities of specialists and hospitals. "This trend has been going on for a long time: but if it continues it is bound to result in over-compensation, unnecessary expense, further dehumanising of medical care, and ultimately the elimination of the general practitioner as a responsible person."

Here some will say: "But none of this is new. Does Dr. COLLINGS imagine that we don't know it?

of a relapse-rate of 50% in cases treated with chloramphenicol was abnormal.

Prof. **Robert Cruickshank** said that the methods for assaying the drug in the blood were at best crude; he thought the best was with the agar-diffusion method. Dr. Liddle's evidence about the organisms in the gall-bladder was interesting. When one was dealing with a drug which could not get into the gall-bladder, one would not expect it to sterilise the bile, and excretion of organisms from the gall-bladder would continue. It would be interesting to know if the carriers had fully functioning gall-bladders. If not, this might be why one did not obtain a cure in these cases.

Dr. **Liddell** replied that in the two carriers he had mentioned, the gall-bladders were examined, and it was found that the dye-stuff was not excreted in these cases. It did appear that delay in emptying the gall-bladder had something to do with the carrier state.

Dr. **White** remarked that chloramphenicol appeared in the bile in conjunction with another substance which rendered it inactive and which was broken down on reaching the gut. In mice chloramphenicol had been given with sulphadiazine, but he did not know of this being tried in man. In the laboratory the drug appeared to be bacteriostatic in vitro, but if combined with a specific antiserum it was bactericidal. Chloramphenicol had been successful in a chimpanzee at the Dublin Zoo when its pneumonia had not responded to penicillin; but the president had implied that chimpanzees and other animals were not likely to receive much chloramphenicol in this country while the Ministry of Health continued to control it and it was in short supply.

Reviews of Books

An Autobiography

Sir ARTHUR KEITH, M.D. Aberd., F.R.S. London: Watts. 1950. Pp. 703. *25s.*

A BOOK by Sir Arthur Keith about his work and himself is not likely to be dull, and this one has most of the qualities which go to make good autobiographical writing. Though not a diary, it is clearly based on one, and it has a Pepys-like sincerity in what he writes of the man he sees in himself. Of his faults he is a merciless critic—faults, it is safe to say, which have seldom been apparent to his many friends and admirers. He is like Pepys too in the skill with which he selects the dramatic incident of the moment.

Thus of his presidential address to the British Association in 1927: "I could evoke no response from the sea of faces in front of me—only a stolid attention; and the feeling grew within me that I was committing the most heinous sin possible from a platform—boring my audience." Hastily he cut his address short, jettisoning his most treasured paragraphs.

A visit by the Prince and Princess of Wales to the museum of the Royal College of Surgeons led to a duel of will between Sir Henry Morris, the president, and Sir Frederick Treves, the courtier. Morris was determined that the royal party's attention should be called to the specimen of the first stone removed from a kidney—his own contribution to the advance of surgery. Treves was equally determined that it should be passed by in silence—and it was.

Like Pepys too, he can sketch his opinion of his contemporaries in a phrase, as when he says of Havelock Ellis, his neighbour in the country, "I never made that projected call and since reading his biography I believe I decided rightly," or of Lord Moynihan, "Lady Moynihan loved the shade and he the sunlight," or of Elliot Smith, "I strove for coöperation but somehow it developed into rivalry."

Perhaps to some it is the story of Keith's boyhood on the Aberdeenshire farm and of his early struggles in London which will most appeal. When he set out from home to seek fame and fortune, it was one Willie Murray who drove him in the cart to the station. "In after years, if any honour came my way, I could always count on a letter from Willie reminding me that it was he and his dung cart which launched me on my career." The book is long and diffuse, intermingling records of domestic events, anatomical investigations, and self analysis; but it will be read.

Occupational Eye Diseases and Injuries

JOSEPH MINTON, F.R.C.S., ophthalmic surgeon to the Hampstead General Hospital; lecturer on industrial ophthalmology at the Royal Institute of Public Health and Hygiene. London: Heinemann Medical Books. 1949. Pp. 184. *21s.*

MR. MINTON has spent some years on the study of industrial eye problems, and the results of his investigations are set down in this book. The subject matter falls into three parts—industrial eye accidents and how they may be avoided, industrial lighting, and the employment of persons of defective eyesight in industry. Industrial eye accidents often end in the law-courts, and many case-histories are quoted to illustrate the awards of these courts; it is evident that the author's sympathies are—commendably but not always impartially—with the injured man. (Would all agree, for instance, that with a detached retina coming on "a few months" after a cut on the eyebrow, there was "no doubt" that the one was due to the other?) The book will be helpful to industrial medical officers, showing them the methods employed in different factories both in preventing and in treating eye accidents.

Diagnosis of Pancreatic Disease

LOUIS BAUMAN, M.D., formerly assistant professor of clinical medicine, Columbia University, New York. *Philadelphia and London: J. B. Lippincott.* 1949. Pp. 74. *40s.*

THIS monograph on pancreatic function tests and their application in the diagnosis of pancreatic disease is based upon the author's 25 years' experience at the Columbia-Presbyterian Clinic, New York. The difficulties and errors inherent in estimating pancreatic function have held up progress in this important problem for many years, and though more recent work on the purification of secretin, and analysis of pancreatic secretion, have greatly advanced knowledge, the book does not suggest much headway. Dr. Bauman gives an account of some 550 pancreatic function tests, using 'Mecholyl' as the pancreatic stimulant; but though his case findings are given in detail it is not easy to find that he has drawn any conclusions of outstanding clinical application. Two short chapters, one on fat-absorption in pancreatic deficiency, and one on serum-amylase estimation, are also included.

Round the Fountain. Pieces from *St. Bartholomew's Hospital Journal*, 1893–1949. (5th ed. Pp. 243.)—In 1893 the various hospital clubs at Barts merged into a students' union with a single monthly journal as its official organ and its rendezvous round the fountain which stands athwart the path, used by Rahere, from the Smithfield to the Little Britain gate. In the centre of the quadrangle, says a modern historian rather unkindly, is a fountain where students are accustomed to sit and gossip away the fine summer days. That they gossip with insight and charm is clear from this gallimaufry (or medley), as the editors call it, which is an essential documentary of the light-hearted side of hospital life.

Perspectives in Neuropsychiatry (H. K. Lewis & Co., 1950. Pp. 236. *15s.*).—Prof. F. L. Golla succeeded Sir Frederick Mott as director of the Central Pathological Laboratory at the Maudsley Hospital, and later took his present appointment as director of the Burden Neurological Institute at Bristol. This little book, designed by some of his associates and past pupils to honour his 70th birthday, carries a collection of fourteen stimulating essays on neuropsychiatric subjects, each signed by a distinguished name. The subjects chosen range through cerebral anatomy, electro-encephalography, the biochemistry of cerebral function, the endocrinology of mental disturbance, the concept of the schema in neurology and psychiatry, the relation of mind and matter to personality, and psychiatric genetics, to forensic psychiatry, aims and methods of treatment, and mental hospital problems. Dr. Derek Richter has edited the collection and contributes one of the essays. All have a background of hard thinking, and ask as much from the reader.

unwilling practitioners to form a group, it is at least equally unwise not to encourage those who want to form one. This kind of spark needs to be fanned, not watered. Perhaps nothing in the report is more significant than the story of the keenness shown by the Scottish practitioners when they got together at their local hospital of a Saturday afternoon.

In conclusion we would say this. The report is the work of one man, necessarily reflecting his predilections, and therefore open to criticism. But if it condemns much in general practice today it also demonstrates the value of general practice to the public, and the need for positive effort if this value is to be preserved. "General practice as we know it could, if we wished, be converted into general practice as we like to imagine it." But do we wish it? The issue is placed squarely before us, and our reaction should be constructive rather than merely defensive. The Collings report, coming at so critical a time, is a major challenge, demanding that we should think straight and act accordingly. We have to decide what the general practitioner should be doing, and then—whatever it is—enable him to do it properly.

Diet in Hypertension

Despite almost fifty years' intensive investigation, the therapeutic value of diet in hypertension is still undecided. This is largely because of confusion of thought on three aspects of the problem. In the first place, as Ayman [1] points out, there is a tendency to overlook the natural history of hypertension, a disorder characterised by wide variations in blood-pressure, and changes in pressure well within the normal range for hypertensives have been taken to indicate that a particular diet is effective. If this error is to be avoided, observation must be continued over many years. The second confusing factor is the lack of careful differentiation of essential hypertension from hypertension secondary to renal disease, particularly nephritis. The third factor is the confusion between essential hypertension without heart-failure and essential hypertension with heart-failure. Thus improvement in hypertensive heart-failure resulting from a low-sodium diet has often been taken to indicate improvement in the hypertension, whereas all that has happened is that the heart-failure has been controlled.

Most attempts to control hypertension by diet have been based on either a low-sodium or a low-protein intake. The low-sodium diet was first popularised by Ambard and Beaujard [2] in 1904, and received a new lease of life from Allen's [3] work in America. Allen, who is still an ardent believer in his régime,[4] emphasised the importance of sodium restriction, whereas other workers put the emphasis on sodium chloride and often regarded the chloride radicle as more important than the sodium. One of the difficulties attached to very low sodium diets, which Allen always appreciated, is that in hypertension associated with renal disease sodium restriction may lead to renal failure and that it is therefore contra-indicated in nephritic hypertension. The rôle of dietary protein in hypertension has been debated for twenty years. Saile [5] compared the diet and blood-pressure in monks of the Carthusian and Carmelite orders with those in Benedictine and Franciscan monks, the first two being vegetarians whereas the second two are not. Saile found that the systolic blood-pressure in the vegetarian monks was on average 30–40 mm. Hg lower than among the non-vegetarian monks. In England Harris [6] was a keen advocate of low-protein diets; but few workers have been able to confirm his results. The work received fresh impetus in the late war from observations on the effect of semistarvation. In Leningrad during the siege the number of cases of hypertension diminished, whereas in the next two years, when food became more plentiful, hypertension became a major medical problem.[7] These observations were confirmed experimentally by the Minnesota experiment of Keys and his colleagues.[8] Among 34 healthy young men submitted for six months to a 1600-calorie diet containing 49 g. of protein, the mean systolic blood-pressure fell by 11·1% and the diastolic by 7·7%. In Budapest, on the other hand, Kohári-Kuchárik [9] found no change in the blood-pressure of 39 patients with essential hypertension after the ten months of rigorous dietetic restriction (predominantly protein) which the city underwent in 1945.

Fresh interest in the effects of diet has been raised by Kempner's enthusiastic reports on his rice diet in hypertension.[10] This diet, which has been described as "combining practically all the theories that have been advanced for the dietary treatment of hypertension, being low in sodium (200 mg.), low in protein (20–25 g.), low in fat (5 g.), and restricting fluid intake to 800–1000 ml.,"[11] consists mainly of rice and fruit juice. In this country it has received a measure of official sanction since the requisite amount of rice can be obtained by patients on presentation of a medical certificate. The diet is ingeniously comprehensive, but neither its originator nor his followers are clear whether it is to be used for the treatment of (*a*) essential hypertension, (*b*) nephritic hypertension, or (*c*) hypertensive heart-failure. Renal failure has arisen through its indiscriminate use, and the original claim that it produces nitrogen balance has been disproved by Schwartz and Merlis.[12] Even those who say that it causes a significant fall in blood-pressure add that careful supervision is necessary [11]; and others have recommended modifications.[13] In one of the more careful studies, Schroeder and his co-workers [14] found no appreciable response to the diet in 13 cases of severe hypertension: "In general, when the disease was relatively advanced and treatment was mandatory neither restriction in salt nor the rice diet appeared to be of much benefit." The position has been ably summed up by Keys and his colleagues [7]:

> "... few workers familiar with the Kempner and similar diets will deny that patients frequently cannot or will

Has he never heard of the Medical Planning Commission, and the British Medical Association's constructive evidence to the Goodenough Committee and its notable reports on health centres and on medical education, all of which have shown awareness of the need for upgrading general practice ?" To which COLLINGS might fairly reply that he is not compiling other people's opinions but expressing his own. He might point out that the actual effect of the admirable sentiments expressed by the B.M.A., by Medical Planning Research, by *The Lancet,* and by so many other people, during the past ten years has evidently been precisely nil, since the state of general practice (he found in 1949) was bad and still deteriorating. And he might add that, though for the first time deliberate planning of our medical services as a whole is possible, the fate of general practice is now being decided—unintentionally, but rapidly and remorselessly—by people who know and care little about it. "It is being determined mainly by the people responsible for hospital and specialist development, and in terms of compensation for recognised, or half-recognised, deficiencies, instead of the correction of these deficiencies." The situation has in fact become critical.

For some time we have been trying to draw attention to this situation. At the beginning of last year we wrote:

> ". . . there are evidently two schools of thought. The first holds that under modern conditions medicine dwells in the hospitals, where alone accurate diagnosis and scientific treatment of major illness is possible. According to this school the emphasis of the new service should be on hospital and specialist services, which will deal with all the illness that matters, and the rôle of the general practitioner is chiefly to feed the hospitals. The second school, on the other hand, regard the investigation and treatment of major illness as secondary to the enormous task of relieving the troubles of everyday life, and of helping people to pursue health: the heart of medicine, they feel, is in general practice, and it is at least as important to have really good general practitioners, bringing medicine to the home, as it is to provide pleasures and palaces for patients who qualify for institutional care. Polemics apart, all will agree that the two parts of clinical medicine are complementary, and that what we have to do is to strike a suitable balance between them; but there certainly seem to be special reasons at present why the hospital school should not be in the ascendant."[1]

Within the profession there is indeed a very real, if unavowed, difference of opinion: on the one hand are those who see no future for the general practitioner except as an appendage to the hospital service, while on the other are those who believe he must be brought back to his former position as a highly responsible doctor. Somewhere between these opposites are those who hold, by no means unreasonably, that ideally the practitioner should concern himself less with organic disease and more with elementary psychotherapy and preventive medicine. Whoever is right, it is certain that the development of the National Health Service cannot be rationally planned without a clear idea of what the function of the practitioner is and should be; and this is the subject that should now be uppermost in the minds of those responsible for the service—not least, perhaps, the Central Health Services Council. Our own opinion that the practitioner must be a man who knows and practises medicine[2] is supported by COLLINGS's argument that, within the present cultural pattern, "the doctor's ability to establish rapport with his patient, and thus place himself in a position to cope with psychological problems, rests largely on his ability to handle physical diseases—not only the minor physical disorder but also, to a great extent, the major one." It is further strengthened by Dr. LESLIE COLE's contention in last week's *British Medical Journal* that the discovery of new and effective remedies, whose immediate administration may mean so much to the patient, has greatly increased the clinical responsibility of the man whose task it is to detect the disease and take initial action. Maybe Dr. COLLINGS is taking an Australian view when he would like to see every practitioner exercising many different skills; but as a minimum we should surely demand conditions under which doctors can and will examine their patients. Can we not also go further and restore the practitioner to his position as the person in medical charge of the case? Always down the breeze comes the siren song of the specialists, *Anything you can do I can do better*; but, as COLLINGS says, we should "firmly resist the conclusion that therefore we must keep on fractionating and specialising." More and more, as the years go by, it is seen that patients need to have some one doctor looking after them; and that is the reason behind COLLINGS's "reactionary thought" that "the patient, as a person, is better off receiving his medical attention, through the undeveloped New Zealand service than he will ever be through any highly developed service depending chiefly on hospitals and specialists."

There is also an economic argument. As we said a few weeks ago, "in terms of expenditure, the cheapest form of medicine is preventive medicine; the next cheapest is efficient care of patients in their homes; and the most expensive is hospital treatment."[3] COLLINGS points out that, "quite apart from human values, it is doubtful whether the policy of concentrating on hospital and specialist care is economically justifiable or even possible, and its hazards will certainly not be lessened by drifting into it." He holds that our programme should be based on the premise that as many people as possible should be kept out of hospitals. But there is at least enough truth in his picture of existing practice to show that changes in its character and conduct will be required if we are to put more rather than less responsibility on the general practitioner. The principal change COLLINGS proposes is a rapid development of professional grouping. His other premise, that medical care should be integrated not fractionated, is related to this because he holds that continuity of medical care "cannot be achieved unless the general practitioner assumes high-level responsibility in a wide range of activities" and that often he cannot safely do this unless he is working with others. "Even the most elementary steps towards organising the present chaos of individual general practice must result in improved medical service and a fairer deal for doctor and patient," and COLLINGS urges that these steps should be taken now, without waiting for some possibly distant future when local authorities may be ready to build the kind of health centres some of them have in mind. In this he is undoubtedly right; and, though it would be most unwise to put pressure on unwilling practitioners to form a group, it is at least equally unwise not to encourage those who want to form one. This kind of spark needs to be fanned, not watered. Perhaps nothing in the report is more significant than the story of the keenness shown by the Scottish practitioners when they got together at their local hospital of a Saturday afternoon.

In conclusion we would say this. The report is the work of one man, necessarily reflecting his predilections, and therefore open to criticism. But if it condemns much in general practice today it also demonstrates the value of general practice to the public, and the need for positive effort if this value is to be preserved. " General practice as we know it could, if we wished, be converted into general practice as we like to imagine it." But do we wish it? The issue is placed squarely before us, and our reaction should be constructive rather than merely defensive. The Collings report, coming at so critical a time, is a major challenge, demanding that we should think straight and act accordingly. We have to decide what the general practitioner should be doing, and then—whatever it is—enable him to do it properly.

Diet in Hypertension

DESPITE almost fifty years' intensive investigation, the therapeutic value of diet in hypertension is still undecided. This is largely because of confusion of thought on three aspects of the problem. In the first place, as AYMAN [1] points out, there is a tendency to overlook the natural history of hypertension, a disorder characterised by wide variations in blood-pressure, and changes in pressure well within the normal range for hypertensives have been taken to indicate that a particular diet is effective. If this error is to be avoided, observation must be continued over many years. The second confusing factor is the lack of careful differentiation of essential hypertension from hypertension secondary to renal disease, particularly nephritis. The third factor is the confusion between essential hypertension without heart-failure and essential hypertension with heart-failure. Thus improvement in hypertensive heart-failure resulting from a low-sodium diet has often been taken to indicate improvement in the hypertension, whereas all that has happened is that the heart-failure has been controlled.

Most attempts to control hypertension by diet have been based on either a low-sodium or a low-protein intake. The low-sodium diet was first popularised by AMBARD and BEAUJARD [2] in 1904, and received a new lease of life from ALLEN's [3] work in America. ALLEN, who is still an ardent believer in his régime,[4] emphasised the importance of sodium restriction, whereas other workers put the emphasis on sodium chloride and often regarded the chloride radicle as more important than the sodium. One of the difficulties attached to very low sodium diets, which ALLEN always appreciated, is that in hypertension associated with renal disease sodium restriction may lead to renal failure and that it is therefore contra-indicated in nephritic hypertension. The rôle of dietary protein in hypertension has been debated for twenty years. SAILE [5] compared the diet and blood-pressure in monks of the Carthusian and Carmelite orders with those in Benedictine and Franciscan monks, the first two being vegetarians whereas the second two are not. SAILE found that the systolic blood-pressure in the vegetarian monks was on average 30–40 mm. Hg lower than among the non-vegetarian monks. In England HARRIS [6] was a keen advocate of low-protein diets; but few workers have been able to confirm his results. The work received fresh impetus in the late war from observations on the effect of semistarvation. In Leningrad during the siege the number of cases of hypertension diminished, whereas in the next two years, when food became more plentiful, hypertension became a major medical problem.[7] These observations were confirmed experimentally by the Minnesota experiment of KEYS and his colleagues.[8] Among 34 healthy young men submitted for six months to a 1600-calorie diet containing 49 g. of protein, the mean systolic blood-pressure fell by 11·1% and the diastolic by 7·7%. In Budapest, on the other hand, KOHÁRI-KUCHÁRIK [9] found no change in the blood-pressure of 39 patients with essential hypertension after the ten months of rigorous dietetic restriction (predominantly protein) which the city underwent in 1945.

Fresh interest in the effects of diet has been raised by KEMPNER's enthusiastic reports on his rice diet in hypertension.[10] This diet, which has been described as " combining practically all the theories that have been advanced for the dietary treatment of hypertension, being low in sodium (200 mg.), low in protein (20–25 g.), low in fat (5 g.), and restricting fluid intake to 800–1000 ml.," [11] consists mainly of rice and fruit juice. In this country it has received a measure of official sanction since the requisite amount of rice can be obtained by patients on presentation of a medical certificate. The diet is ingeniously comprehensive, but neither its originator nor his followers are clear whether it is to be used for the treatment of (*a*) essential hypertension, (*b*) nephritic hypertension, or (*c*) hypertensive heart-failure. Renal failure has arisen through its indiscriminate use, and the original claim that it produces nitrogen balance has been disproved by SCHWARTZ and MERLIS.[12] Even those who say that it causes a significant fall in blood-pressure add that careful supervision is necessary [11]; and others have recommended modifications.[13] In one of the more careful studies, SCHROEDER and his co-workers [14] found no appreciable response to the diet in 13 cases of severe hypertension: " In general, when the disease was relatively advanced and treatment was mandatory neither restriction in salt nor the rice diet appeared to be of much benefit." The position has been ably summed up by KEYS and his colleagues [7]:

> " . . . few workers familiar with the Kempner and similar diets will deny that patients frequently cannot or will

not adhere to such restrictions. Out of the Minnesota and Leningrad experience grows the possibility that such a patient may be worse off when he modifies or abandons his dietary restrictions than he was before the treatment was initiated . . . . Patients so selected [i.e., for the Kempner diet] should be warned beforehand that once instituted the regimen must be followed carefully, and that modification, particularly if sudden, may be dangerous."

For the practising clinician, the position seems to be as follows. The one definite indication for dietetic restriction in hypertension is obesity. There is overwhelming evidence [15] that the prognosis in the obese hypertensive is worse than in the hypertensive of normal or subnormal weight. Every obese hypertensive should therefore be given a moderate reducing diet—e.g., 1100 calories a day—which will gradually bring down his weight. If he is a heavy salt-eater, then salt should also be restricted. In hypertensive heart-failure the diet should be modified as for all cases of congestive heart-failure—i.e., low sodium and restricted fluids. Particular care should be taken in hypertensive patients liable to indigestion; for hypertensives are in any case more prone to coronary disease than are normotensive people, and there is some evidence that disturbed gastric function may impair the coronary circulation. This will usually mean putting the patient on a bland diet. Chapman and Gibbons,[16] who have reviewed the whole field of diet in hypertension, are convinced that in some hypertensives the Allen or Kempner régime causes a significant fall in blood-pressure; but to most of us the evidence still does not seem firm enough to justify a doctor putting his hypertensive patients on a dull and monotonous diet which is also difficult to acquire and prepare.

Sex Hormones in Herbage

About 1941, sheep farmers in Western Australia became aware of a new threat to the health of their animals. The fertility of flocks grazing the pastures in this area rather suddenly began to decline to such an extent as to call for urgent scientific investigation. On some farms the reproductive difficulties soon became so acute that the owners gave up sheep-breeding altogether as unprofitable. The picture which emerged at the outset, as described by Bennetts,[17] resolved itself into three seemingly distinct affections of the ewes. These were: (1) sterility in spite of repeated mating with rams of proved fertility, associated with cystic glandular hyperplasia of the endometrium; (2) dystocia due to fœtal death and consequent absence of parturition; and (3) uterine prolapse, usually occurring some months after the lambing season, and often seen in non-breeding ewes and even virgin females.

This emergency, of grave if localised economic importance, was tackled with commendable vigour and thoroughness, a team of workers being appointed by the C.S.I.R. and the department of agriculture of Western Australia to study the trouble from various aspects. Quite early on it seemed likely to be nutritional rather than infectious in origin and an interesting relationship soon became apparent. For some years efforts had been made to improve the Western Australian pastures by introducing an early variety of subterranean clover, *Trifolium subterraneum L.* var. *Dwalganup*. This plant found local conditions so much to its liking that in many pastures it became the dominant species. And it was on precisely these luxuriant pastures, which for a few deceptive years had seemed to be so outstanding a tribute to the skill of the agrostologist, that the breeding troubles occurred. A significant and profitable clue to the probable nature of the nutritional factor involved was provided by some other remarkable effects described by Bennetts et al.[18] in sheep grazing on this clover. Though rams showed no clinical abnormalities and their breeding powers were unimpaired, wethers (castrated males) often exhibited unmistakable metaplastic changes in the accessory reproductive organs, of which the most striking was the prominence of a cystic gland lined by epithelium homologous with that of the vagina. This pointer towards sex-hormone imbalance was decisively reinforced by the most significant clue of all—the finding of abnormal teat and udder development not only in virgin females but also in wethers. In the females this was extensive enough to result in fairly copious lactation. Since it is now well known that udder growth and lactation can be induced in farm animals by treatment with œstrogens,[19] the team of investigators justifiably inferred that the affected sheep were ingesting a potent œstrogen from the pastures, or at least some substance which so modified their hormone balance as to establish an excess of œstrogen. On this view the whole complex of clinical syndromes fell neatly into place. It was not long before an œstrogenic extract was prepared from subterranean clover by Curnow et al.[20] and the substance involved is now being investigated both in Australia and also by a member of the original team working with Prof. E. C. Dodds at the Courtauld Institute of Biochemistry in London.

These remarkable findings clearly open up a new field with wider applications than were at first apparent. For example, the fact that herbage may contain an œstrogenic substance in sufficient concentrations to evoke a response in the mammary glands of grazing animals suggested that the presence of œstrogens in English pastures might be connected with the flush of milk and improvement in its composition often observed when cows are turned out to spring grass. Indeed, workers at the National Institute for Research in Dairying and the Courtauld Institute of Biochemistry have jointly shown [21] that potent œstrogens can be extracted from English herbage. This coöperative investigation is now being pursued side by side with the study of the œstrogen of Western Australian clover, and it has already produced further evidence of significant amounts of œstrogenic material in English pasture plants.[22]

The idea that plants may contain animal sex hormones is not new; Loewe and Spohr [23] demonstrated œstrogens in plants as long ago as 1926 and they have

since been identified in various species. What is new and important is the finding that, exceptionally, pasture plants can contain enough to have pathological effects on grazing animals. This poses the question as to the part played by pasture sex hormones ingested regularly by herbivores in subtoxic amounts, in the regulation, not only of fertility but of growth, fattening, and lactation, all of which are under endocrine control. These aspects merit serious study in relation to modern techniques of pasture improvement, particularly since the successful efforts to improve the pastures in Western Australia had such unexpected and undesirable consequences. So we may hope to apply the knowledge gained from this strange happening to the benefit of mankind. This work would clearly come within the scope of the concerted international effort in the field of steroid science that Sir ROBERT ROBINSON called for in his anniversary address to the Royal Society.[24]

Annotations

DEATH ON THE BEDPAN

STRAINING at stool may be a fatal activity for the elderly, the hypertensive, and those with defective hearts. A group of American workers [25] have looked up the records of all patients in Cincinnati General Hospital who died on bedpans and came to necropsy between 1936 and 1946; and they have also studied the effects of "bearing down" on the blood-pressure and electrocardiograms of normal people and patients with heart-disease. There were 11 bedpan deaths recorded among notes on 6700 necropsies; and no doubt there were more of them than this at the hospital during the ten years under review, for not all cases ending fatally were examined post mortem. All the patients except one (a child of six with rheumatic carditis) were over forty, and 5 of them were over sixty; most of them had serious organic heart-disease. The accidents which overtook them were such things as rupture of a dissecting aneurysm, cerebral or subarachnoid hæmorrhage, myocardial infarction, pulmonary embolism, or other accidents associated with a damaged heart or vessels.

Those normal subjects and patients who provided material for the practical study were asked to take a deep breath, hold it, and strain down vigorously as if trying to have a bowel movement. Electrocardiograms taken before, during, and after the strain were correlated with blood-pressure readings from the radial artery, and with records of intrapleural pressures measured by water manometers on patients with a pneumothorax. The systolic blood-pressure fell slightly as the deep breath was taken; but as the straining began systolic and diastolic pressures rose abruptly—from 147/80 to 203/142 mm. Hg (average in 10 subjects). While the strain lasted, both pressures slowly fell, but since the systolic fell more than the diastolic, the pulse-pressure was much reduced by the end of the period of strain—sometimes almost disappearing altogether. At the moment when the strain ended the blood-pressure fell still further—to an average of 84/58. Within 5 seconds, however, the "after-fling" came into play, the pressure rising quickly again to well above the normal level. Normal blood-pressure was only regained some 30 sec. later. Pressure curves made from the left ventricle and the femoral artery, of a patient with a defect of the ventricular septum, showed that the blood-pressure changes matched those in the left ventricle; similar types of pressure curve were obtained from the right ventricle, right auricle, superior and inferior vena cava, and also the rectum and bladder. Intrathoracic pressure fell slightly as the breath was taken, rose abruptly by some 20 mm. Hg as the strain began, and maintained a plateau at that level until the strain ended, when it fell at once to normal (average in 10 patients with a pneumothorax).

The dangerous moment came with the after-fling; for during the first rise of blood-pressure, at the onset of strain, the great vessels were supported on the outside by the rise of intrathoracic pressure. During the after-fling the intrathoracic pressure had already fallen to normal, and thus there was nothing to buffer the vessel walls against the strain. The authors suggest that the fall in pulse-pressure towards the end of bearing down may favour intravascular clotting and also sharply reduce the flow in the coronary arteries. Moreover sudden changes in intravascular pressure may dislodge thrombi not firmly attached to the walls of vessels. The electrocardiogram showed that the heart-rate increased slightly during the intake of breath, slowed, and then increased again during the bearing-down period; at the moment of relaxation bradycardia developed in normal people, and in some ectopic rhythms appeared as well. Bradycardia also developed in patients with rheumatic heart-disease, but was less common in hypertensive or arteriosclerotic patients. The changes in rate and rhythm were abolished in normal subjects by atropine gr. $^{1}/_{75}$ given intravenously. Since the study shows that cardiac arrhythmias, vascular hæmorrhage, and pulmonary embolism are the common causes of death on the bedpan, the authors comment that the avoidance of constipation, early ambulation after operations (to reduce the chance of venous thrombosis), and atropine may be the means of reducing such deaths. It looks as though the best friend of the elderly patient with morbus cordis is a gentle laxative.

ACTION OF EMETINE

FOR forty years emetine has been looked on as a specific for amœbiasis. That it will not reach the amœba in every tissue in which this parasite is lodged has, of course, been recognised at least since the 1914–18 war, though this limitation was rediscovered many times during and after the recent war by physicians new to tropical experience. However, in an organ such as the liver, where emetine reaches a relatively high concentration and comes into very close contact with the amœba, its action is more certain. Even when an abscess has already developed, emetine will stop the active processes in the surrounding liver tissues, symptoms will rapidly subside, and the abscess itself, already sterile, will usually dry up; but in amœbic hepatitis where the amœba is fighting an evenly matched battle with the liver tissues, the effect is more dramatic. Here even a single injection of one grain of the alkaloid will often tip the balance in favour of the tissues and cause a sharp clinical improvement. A course of three injections is regarded by many workers as a very useful therapeutic test.

The frequency with which a hepatitis in tropical countries responds in this way to emetine has been explained in two ways: some workers claim that it indicates the frequency with which the liver is involved in amœbiasis; others hold that emetine has a specific action on the liver whatever micro-organism is infecting it. From time to time the latter school of thought recruits a fervent disciple, such as Professor Melchior, of Ankara University, who has now gone even further in his enthusiasm for emetine and has used it in infections of other organs and tissues—e.g., malignant furuncle of the lip,[1] purulent traumatic meningitis,[2] abscesses of

This will usually mean putting the patient on a bland diet. Chapman and Gibbons,[16] who have reviewed the whole field of diet in hypertension, are convinced that in some hypertensives the Allen or Kempner régime causes a significant fall in blood-pressure; but to most of us the evidence still does not seem firm enough to justify a doctor putting his hypertensive patients on a dull and monotonous diet which is also difficult to acquire and prepare.

Sex Hormones in Herbage

About 1941, sheep farmers in Western Australia became aware of a new threat to the health of their animals. The fertility of flocks grazing the pastures in this area rather suddenly began to decline to such an extent as to call for urgent scientific investigation. On some farms the reproductive difficulties soon became so acute that the owners gave up sheep-breeding altogether as unprofitable. The picture which emerged at the outset, as described by Bennetts,[17] resolved itself into three seemingly distinct affections of the ewes. These were: (1) sterility in spite of repeated mating with rams of proved fertility, associated with cystic glandular hyperplasia of the endometrium; (2) dystocia due to fœtal death and consequent absence of parturition; and (3) uterine prolapse, usually occurring some months after the lambing season, and often seen in non-breeding ewes and even virgin females.

This emergency, of grave if localised economic importance, was tackled with commendable vigour and thoroughness, a team of workers being appointed by the C.S.I.R. and the department of agriculture of Western Australia to study the trouble from various aspects. Quite early on it seemed likely to be nutritional rather than infectious in origin and an interesting relationship soon became apparent. For some years efforts had been made to improve the Western Australian pastures by introducing an early variety of subterranean clover, *Trifolium subterraneum L.* var. *Dwalganup*. This plant found local conditions so much to its liking that in many pastures it became the dominant species. And it was on precisely these luxuriant pastures, which for a few deceptive years had seemed to be so outstanding a tribute to the skill of the agrostologist, that the breeding troubles occurred. A significant and profitable clue to the probable nature of the nutritional factor involved was provided by some other remarkable effects described by Bennetts et al.[18] in sheep grazing on this clover. Though rams showed no clinical abnormalities and their breeding powers were unimpaired, wethers (castrated males) often exhibited unmistakable metaplastic changes in the accessory reproductive organs, of which the most striking was the prominence of a cystic gland lined by epithelium homologous with that of the vagina. This pointer towards sex-hormone imbalance was decisively reinforced by the most significant clue of all—the finding of abnormal teat and udder development not only in virgin females but also in wethers. In the females this was extensive enough to result in fairly copious lactation. Since it is now well known that udder growth and lactation can be induced in farm animals by treatment with œstrogens,[19] the team of investigators justifiably inferred that the affected sheep were ingesting a potent œstrogen from the pastures, or at least some substance which so modified their hormone balance as to establish an excess of œstrogen. On this view the whole complex of clinical syndromes fell neatly into place. It was not long before an œstrogenic extract was prepared from subterranean clover by Curnow et al.[20] and the substance involved is now being investigated both in Australia and also by a member of the original team working with Prof. E. C. Dodds at the Courtauld Institute of Biochemistry in London.

These remarkable findings clearly open up a new field with wider applications than were at first apparent. For example, the fact that herbage may contain an œstrogenic substance in sufficient concentrations to evoke a response in the mammary glands of grazing animals suggested that the presence of œstrogens in English pastures might be connected with the flush of milk and improvement in its composition often observed when cows are turned out to spring grass. Indeed, workers at the National Institute for Research in Dairying and the Courtauld Institute of Biochemistry have jointly shown [21] that potent œstrogens can be extracted from English herbage. This coöperative investigation is now being pursued side by side with the study of the œstrogen of Western Australian clover, and it has already produced further evidence of significant amounts of œstrogenic material in English pasture plants.[22]

The idea that plants may contain animal sex hormones is not new; Loewe and Spohr [23] demonstrated œstrogens in plants as long ago as 1926 and they have leucotactic effect. In addition, while a single dose of cord factor causes no ill effect, repeated small injections in mice lead to death after the ninth day. Severe hæmorrhages were seen in the lungs of these animals and the agent appeared to damage the capillaries, though the mode of action was not clear. The fact that at least two injections are needed to cause tissue damage suggests the possibility of some type of sensitisation. The American workers have not been able to show that virulent tubercle bacilli stripped of their lipid coat, fall an easy prey to the body's defences in the same way as naked pneumococci. Stripped tubercle bacilli still produce infection, though its progress is slow. Clearly it is not possible to equate virulence with cord substance, but there can be little doubt that it is an indispensable covering for the fully virulent tubercle bacillus.

FORESIGHT IN THE U.S.A.

THROUGH the smoke of the battle over medical services in the United States one can discern agreement at least on certain fundamentals. For example, everybody wants to see more hospitals provided, particularly in rural areas, and everybody would like coördination of hospital and health-services areas. Also everybody agrees on the need to have all relevant facts; and to this end a number of valuable and non-controversial reports have been produced. The latest of these[1] gives estimates of the number of doctors that will be required in the future. Prepared by Dr. Joseph Mountin, assistant surgeon-general to the United States Public Health Service, and Elliott Pennell and Anne Berger, statisticians, it follows an earlier work entitled "Health Service Areas: Requirements for General Hospitals and Health Centres."

The central purposes of the report are "to describe the existing distribution picture for physicians against . . . a pattern of medical service areas, to present estimates of the number of physicians that might be utilised as health services are extended more uniformly throughout the Nation, and to forecast possible physician resources." The authors begin by tracing the expansion in the number of doctors practising in the United States since the turn of the century. From a total of 134,000 in 1909 this has grown to an estimated total of 200,000 in 1949. Even so, however, the increase has not kept pace with the growth of the general population. Thus in 1909 there were 149 doctors per 100,000 persons and in 1949 only 137. Side by side with this growth has been the increasing trend towards specialisation: in 1923 some 15,000 doctors limited their practice to a specialty, but last year the estimated figure was 50,000. During this time the inequalities of distribution of doctors have become more pronounced and the New England and Middle Atlantic States have now beaten the claim of the Pacific States to the highest doctor-patient ratio, with 174 per 100,000. On the other hand, the South Central States have declined to 99 per 100,000. The report emphasises that doctors are attracted to areas with relatively high per-capita incomes, and within these areas to centres of population generously supplied with hospital facilities. Such facilities, even apart from per-capita income, serve to attract and retain physicians.

The principle is accepted without question that hospital or related facilities should be accessible to every doctor, and that even in rural areas they should consist of a small hospital or health centre. It is also regarded as axiomatic that doctors in all locations should have access, directly or indirectly, to the physical facilities of a complete hospital system. On this understanding an attempt is made to estimate the number of doctors required by 1960. In 1940 a quarter of the inhabitants of the United States lived in regions which had 146 or more doctors per 100,000; a third lived in regions with a doctor-patient ratio below 146 but above 136; and the remainder lived in areas with a ratio below 136 but above 118. The estimated requirement for 1960, based on raising regional ratios to 146 if below that level and keeping them constant if above it, is 241,172. The corresponding requirements for levels of 136 and 118 are 229,785 and 213,523 respectively. This excludes doctors employed by the Federal government, the Veterans Administration, the public-health services, and the defence services. (If the needs of the various Federal agencies are included and allowances made for retirement the totals for 1960 become 272,172, 260,785, and 244,532 respectively.) On present output the medical schools will barely be able to maintain an over-all ratio of 136, and "even if another decade were allowed to take care of expected deficits, present medical training facilities would still have to be expanded considerably." On the other hand, it is expected that of the doctors available in 1960 no fewer than 70,640 will have been trained as specialists, compared with the highest estimated requirement of 58,540. The only type of specialist who may be scarce is the tuberculosis expert.

As a step towards discovering the deficiencies which have to be made good in providing adequate medical services this report is valuable. It can be criticised on the grounds that it does not deal in detail with under-doctored districts; but it is refreshingly modest, and the authors content themselves with their estimated figures. By implication they make it clear that the difficulty of getting doctors to settle in under-doctored areas can be largely met by providing better hospital facilities and by the integration of hospital and health services. On this score alone the report should do good, in helping to prevent in the U.S.A. the rift between hospital and health services now so painfully evident in this country. It demonstrates also the value of thinking ahead: for the estimates will enable existing medical schools to plan precisely for the next ten years and will assist the authorities to decide what extensions and new schools are required. Political and administrative action will thus be based on fact rather than expediency.

COMPOSITION OF MATCH HEADS

IT appears that the children of Victoria, Australia, are addicted to eating the heads off matches, especially the coloured ones. A firm of match manufacturers (Bryant and May Ltd.) has been receiving so many telephone calls from doctors about the composition of match heads, that the managing director has sent to the Victorian branch of the British Medical Association a letter giving the information and asking that it be published.[1] The main chemical in the heads of safety matches is, he says, potassium chlorate (60 match heads containing about half a gramme), and there are smaller amounts of glue, sulphur, and what are claimed to be "inert" filling materials like powdered silica and asbestine. In the coloured matches is a small amount of an aniline dye, of the type used in foodstuffs. No phosphorus is used in the safety matches. The heads of wax matches contain the same ingredients as those in safety matches, with the addition of a "non-poisonous compound of phosphorus and sulphur," presumably phosphorus sesquisulphide. It is pointed out that white phosphorus has not been used for over 50 years in these "strike anywhere" compositions.

The striking surface of the match-boxes contains red or amorphous phosphorus, which is said by the manufacturers to be non-poisonous and to pass unchanged joints, puerperal peritonitis, septicæmia, cholecystitis and cholangitis,[3] and appendicitis. He has gained the support of Prof. Corinaldesi, of Bologna, who has used emetine with success in a large series of surgical and gynæcological infections, many of a grave nature.[4] Dr. Bernoulli [5] demonstrated that, in vitro, emetine had little lethal action on streptococci, staphylococci, pneumococci, and coliform organisms, but that it had a pronounced bacteriostatic action. Others have noted striking dramatic effects of emetine in acute appendicitis, but in many such cases the amœba has been found to be the cause. In circumstances where it is at all possible to delay operation, some surgeons in the tropics prefer to give emetine first in cases of acute appendicitis, since the results of operation on the amœba-infected appendix are sometimes very unsatisfactory, whereas emetine treatment often obviates operation.

[1] Public Health Bulletin No. 305. Health Service Areas: Estimates of Future Physician Requirements. Federal Security Agency, Public Health Service, Washington, D.C.

[1] *Med. J. Aust.* Dec. 31, 1949, p. 958.

If Professor Melchior is right and emetine is curative in non-amœbic liver infections, we can no longer assume that response to emetine means that a hepatitis is necessarily of amœbic origin; and one of our few diagnostic criteria for this condition will no longer be valid. On the other hand it is now a good many years since he made his first observations on the non-specific action of emetine in 1943, and it is a little surprising that so few others have observed the protean effect of a drug which was used so extensively throughout the war years.

HOME HELPS FOR THE TUBERCULOUS

IN our correspondence columns Miss E. D. Andrews describes the difficulty a tuberculous patient—even when non-infectious—may experience in getting help in the home during illness. Such patients have more difficulty than most in gaining admission to hospital; and at home, she suggests, they are unable to get even the small amount of help available to other sick people.

General provision for the tuberculous is inadequate, as we recently pointed out [6]; and it seems that here is another way in which they may be penalised. All the same, the position of the health authorities is not easy, and the difficulty certainly does not arise from lack of good will. She writes from London; and the London County Council have taken much advice on the very point she raises. Would it be justifiable to send home helps into the households of tuberculous patients without giving them some warning and choice? The L.C.C. thought not, and therefore decided that they would send only volunteers to such households; they decided, too, that if possible such helps should be over the age of 45; that if possible they should not work in tuberculous households for more than 3 months at a time; that their chests should be radiographed at the discretion of the divisional medical officers; and that each should receive a short note on precautionary measures.

A further suggestion that the chest of every home help should be periodically radiographed has met with the objection that this practice would prove alarming and dry up the source of voluntary labour. Yet we are not at all certain that this fear is well founded: people are far more commonly reassured than alarmed by precautions for their protection, as we all learned in the war. In 1934, when Geer,[7] in St. Paul, U.S.A., instituted his precautions for the protection of nurses against tuberculosis, everyone predicted a decline in recruitment; but in fact from the time they were started the hospital never lacked staff. Clearly, though the L.C.C. have taken sensible steps to protect their home helps properly, the problem is not yet solved; and it is a problem of growing importance. If the domiciliary care of the tuberculous is to be considerably increased, as we believe it should, it looks as though we should have to develop, somehow or other, a volunteer home-help service specially for them. Much might be done perhaps by making a clearer distinction between the open and the closed case. Once people learn that the closed case is not infective they will be far less likely to hang back; and this change of attitude would be of help to tuberculous patients everywhere.

MORPHOLOGY AND VIRULENCE

BACTERIOLOGISTS have long been aware that the morphology of organisms and their colonies may be related to virulence. Smooth and rough colony variations often connote virulent and non-virulent phases, and the loss of pneumococcal capsule brings both roughness and loss of virulence in its train.

The pattern of growth of *Myco. tuberculosis* has often been studied, and it is well established that on solid or in liquid media virulent strains and also some B.C.G. strains form tight bundles or cords of organisms lying parallel to each other; avirulent strains, on the other hand, merely grow in irregular clumps. The colonial forms which any single strain of tubercle bacillus may take on different media are notoriously variable, but Dubos [1] made it clear that in a large number of strains cord formation and virulence were closely associated and that the tighter the cord the greater the virulence. Cord formation can be enhanced by chick-embryo extract or diminished by adding certain surface-acting agents. Such a characteristic mode of growth of virulent tubercle bacilli could presumably depend either on chemical or physical forces, or on both. A chemical substance present in virulent but not in avirulent strains could bind the bacilli in parallel; and Dubos and Middlebrook [2] demonstrated by a colour reaction that such a cord substance exists. Bloch [3] has now shown that the bacillary cords can readily be disrupted when virulent strains are suspended in hydrocarbons, such as paraffin oil or petroleum ether. So long as the bacilli are surrounded by a watery layer they are protected from disruption, but in a lipophylic phase the binding substance readily goes into solution leaving the bacilli dispersed as single organisms or small clumps. Bloch has thus been able to isolate in crude form the binding or cord substance and to study some of its properties. There seems little doubt that it differs from the numerous other fractions which have been isolated from tubercle bacilli, and that it is not concerned in sensitivity to tuberculin. Avirulent organisms do not possess the cord substance; and virulent organisms, from which it has been stripped, are still able to grow on culture media. Bloch [4] also shows that the possession of the substance prevents virulent strains from reducing methylene-blue, while in avirulent or stripped organisms the permeability of the bacterial surface permits the cell's enzyme to make contact with its substrate.

While there is good reason to believe that the lipid substance and virulence are associated properties it is much harder to show what part cord factor plays in the disease itself. Organisms already tightly packed together may be better able to withstand attack, and we do know that dispersed organisms in a test-tube are more readily killed than those in solid phalanx. The American workers, however, had already shown that when leucocytes phagocytose virulent tubercle bacilli the white cell loses much of its power to migrate on plasma gel while avirulent organisms migrate freely. Cord factor itself has been shown to have both a leucotoxic and a

leucotactic effect. In addition, while a single dose of cord factor causes no ill effect, repeated small injections in mice lead to death after the ninth day. Severe hæmorrhages were seen in the lungs of these animals and the agent appeared to damage the capillaries, though the mode of action was not clear. The fact that at least two injections are needed to cause tissue damage suggests the possibility of some type of sensitisation. The American workers have not been able to show that virulent tubercle bacilli stripped of their lipid coat, fall an easy prey to the body's defences in the same way as naked pneumococci. Stripped tubercle bacilli still produce infection, though its progress is slow. Clearly it is not possible to equate virulence with cord substance, but there can be little doubt that it is an indispensable covering for the fully virulent tubercle bacillus.

FORESIGHT IN THE U.S.A.

THROUGH the smoke of the battle over medical services in the United States one can discern agreement at least on certain fundamentals. For example, everybody wants to see more hospitals provided, particularly in rural areas, and everybody would like coördination of hospital and health-services areas. Also everybody agrees on the need to have all relevant facts: and to this end a number of valuable and non-controversial reports have been produced. The latest of these[1] gives estimates of the number of doctors that will be required in the future. Prepared by Dr. Joseph Mountin, assistant surgeon-general to the United States Public Health Service, and Elliott Pennell and Anne Berger, statisticians, it follows an earlier work entitled "Health Service Areas: Requirements for General Hospitals and Health Centres."

The central purposes of the report are "to describe the existing distribution picture for physicians against . . . a pattern of medical service areas, to present estimates of the number of physicians that might be utilised as health services are extended more uniformly throughout the Nation, and to forecast possible physician resources." The authors begin by tracing the expansion in the number of doctors practising in the United States since the turn of the century. From a total of 134,000 in 1909 this has grown to an estimated total of 200,000 in 1949. Even so, however, the increase has not kept pace with the growth of the general population. Thus in 1909 there were 149 doctors per 100,000 persons and in 1949 only 137. Side by side with this growth has been the increasing trend towards specialisation: in 1923 some 15,000 doctors limited their practice to a specialty, but last year the estimated figure was 50,000. During this time the inequalities of distribution of doctors have become more pronounced and the New England and Middle Atlantic States have now beaten the claim of the Pacific States to the highest doctor-patient ratio, with 174 per 100,000. On the other hand, the South Central States have declined to 99 per 100,000. The report emphasises that doctors are attracted to areas with relatively high per-capita incomes, and within these areas to centres of population generously supplied with hospital facilities. Such facilities, even apart from per-capita income, serve to attract and retain physicians.

The principle is accepted without question that hospital or related facilities should be accessible to every doctor, and that even in rural areas they should consist of a small hospital or health centre. It is also regarded as axiomatic that doctors in all locations should have access, directly or indirectly, to the physical facilities of a complete hospital system. On this understanding an attempt is made to estimate the number of doctors required by 1960. In 1940 a quarter of the inhabitants of the United States lived in regions which had 146 or more doctors per 100,000: a third lived in regions with a doctor-patient ratio below 146 but above 136; and the remainder lived in areas with a ratio below 136 but above 118. The estimated requirement for 1960, based on raising regional ratios to 146 if below that level and keeping them constant if above it, is 241,172. The corresponding requirements for levels of 136 and 118 are 229,785 and 213,523 respectively. This excludes doctors employed by the Federal government, the Veterans Administration, the public-health services, and the defence services. (If the needs of the various Federal agencies are included and allowances made for retirement the totals for 1960 become 272,172, 260,785, and 244,532 respectively.) On present output the medical schools will barely be able to maintain an over-all ratio of 136, and "even if another decade were allowed to take care of expected deficits, present medical training facilities would still have to be expanded considerably." On the other hand, it is expected that of the doctors available in 1960 no fewer than 70,640 will have been trained as specialists, compared with the highest estimated requirement of 58,540. The only type of specialist who may be scarce is the tuberculosis expert.

As a step towards discovering the deficiencies which have to be made good in providing adequate medical services this report is valuable. It can be criticised on the grounds that it does not deal in detail with under-doctored districts; but it is refreshingly modest, and the authors content themselves with their estimated figures. By implication they make it clear that the difficulty of getting doctors to settle in under-doctored areas can be largely met by providing better hospital facilities and by the integration of hospital and health services. On this score alone the report should do good, in helping to prevent in the U.S.A. the rift between hospital and health services now so painfully evident in this country. It demonstrates also the value of thinking ahead: for the estimates will enable existing medical schools to plan precisely for the next ten years and will assist the authorities to decide what extensions and new schools are required. Political and administrative action will thus be based on fact rather than expediency.

COMPOSITION OF MATCH HEADS

IT appears that the children of Victoria, Australia, are addicted to eating the heads off matches, especially the coloured ones. A firm of match manufacturers (Bryant and May Ltd.) has been receiving so many telephone calls from doctors about the composition of match heads, that the managing director has sent to the Victorian branch of the British Medical Association a letter giving the information and asking that it be published.[1] The main chemical in the heads of safety matches is, he says, potassium chlorate (60 match heads containing about half a gramme), and there are smaller amounts of glue, sulphur, and what are claimed to be "inert" filling materials like powdered silica and asbestine. In the coloured matches is a small amount of an aniline dye, of the type used in foodstuffs. No phosphorus is used in the safety matches. The heads of wax matches contain the same ingredients as those in safety matches, with the addition of a "non-poisonous compound of phosphorus and sulphur," presumably phosphorus *sesquisulphide*. It is pointed out that white phosphorus has not been used for over 50 years in these "strike anywhere" compositions.

The striking surface of the match-boxes contains red or amorphous phosphorus, which is said by the manufacturers to be non-poisonous and to pass unchanged through the alimentary tract. Schwarz et al.,[2] who give a more complete account of the chemicals used in match manufacture, say that bone necrosis does occur from the use of red phosphorus, though few cases have been reported. The sesquisulphide is less toxic, but not completely harmless. The banning by the Berne Convention (1906) of the use of white phosphorus in the manufacture of matches is rightly regarded as a notable advance in preventive medicine. And the neo-Victorian children, who like the "taste of pink," will come to less harm than their Victorian forebears would have done if they had committed similar dietary indiscretions.

CHEMOTHERAPEUTIC LESSONS FROM BOVINE MASTITIS

OVER 70 years ago Dr. Milroy in his "suggestions" for lectures at the Royal College of Physicians emphasised the valuable information likely to accrue from studies on comparable diseases in man and animals; but only in recent times have the natural infections of animals, as opposed to those experimentally induced, received detailed attention. Some of these natural infections may be transmitted to man, and uncontrolled diseases in domestic animals sometimes have a serious effect on the national economy. An obvious example of the latter is bovine mastitis. Although mastitis occurs as a human infection, it is fortunately not so common as the disease in cattle, though the basic pathology is similar. Bovine mastitis occurs in both acute and chronic forms. The acute disease when not fatal commonly causes disorganisation or destruction of the affected quarters, while the chronic form has a serious effect on the cow's general well-being and milk yield. Several well-recognised pathogens may cause the infection, the commonest being *Streptococcus agalactiæ*, which can be recovered from acute or chronic cases. Other streptococci, including strains found in human disease, may be found, particularly in acute infections. *Staphylococcus aureus* causes about 20% of all the cases of mastitis, among which are the most serious. These staphylococci are morphologically similar to many seen in human infections.

The clinical efficacy of the sulphonamides in streptococcal mastitis is irregular; but penicillin injected up the teat canal, alone or combined with sulphanilamide by mouth, has proved strikingly successful. *Streptococcus agalactiæ* infection has been eradicated from many herds in this way. Systemic penicillin does not provide a sufficient concentration in the udder to deal adequately with the local infection. As in the human disease, staphylococcal infections have often proved difficult to treat satisfactorily, even when the organism is sensitive to penicillin in vitro. The result in dairy herds has been an increasing number of subacute or chronic cases producing contaminated milk. As Thrower[3] has pointed out, pasteurisation alone provides an undesirable safeguard against risks of this kind; it may delay the proper clearing-up of herds, and also retard improvements in milking technique and teat hygiene which will reduce the incidence of cross-infection.

Other compounds which may be useful in the resistant cases are being tried, and the findings are instructive from the point of view of chemotherapy in general. Dibromopropamidine ('M. & B. 1270') has been shown to be bactericidal in high dilutions for staphylococci and streptococci,[4] including those recovered from cases of bovine mastitis. When, however, it was tested against these in the presence of milk, the concentration necessary for bacteriostasis was found to be five hundred times that required in a milk-free medium. Analysis demonstrated that the inhibitory factor was lecithin.[5] This inhibitory effect of lecithin has been observed independently by Elson.[6] Together dibromopropamidine and sulphathiazole, in the correct proportions, seem to have a synergistic effect. After repeated experiments it was found that a mixture of dibromopropamidine and sulphathiazole in the proportions of 4:1 was four times as active in a milk medium as dibromopropamidine alone. A trial of the combination of the two in arachis oil and beeswax injected into the udder gave clinical results in keeping with the experimental findings and quite as good as those with penicillin given locally.

The tendency of natural fluids to interfere with the bactericidal powers of antibacterial substances has been troublesome since the early days of chemotherapy, but apparently not much attention has been paid to the individual factors responsible. This work on dibromopropamidine is a step in the right direction. There are, incidentally, good reasons for avoiding the use of penicillin in the udder. The milk from a cow treated for mastitis may contain enough penicillin to interfere with the action of the streptococci used as "starters" in cheese-making, and it will give an optimistically fallacious answer to the methylene-blue test for keeping quality.[7] Few changes have brought as much benefit to mankind in recent years as the reductions in the price of penicillin; perhaps there is good reason for not making it any cheaper.

ROYAL VISIT TO THE SURGEONS

ON March 20 the Queen visited the Royal College of Surgeons to be admitted to the honorary fellowship. In welcoming her, Sir Cecil Wakeley described the ceremony as the first and foremost event in the celebration of the 150th anniversary of the granting of the first royal charter to the college in 1800. With the Queen's name at the head of their honorary fellows, he continued, they would go forward with renewed vigour and firmer confidence in performing the duty laid upon them by George III—"the due promotion and encouragement of the Study and Practice of the Art and Science of Surgery." The Queen, who was sponsored by the vice-presidents of the college, Sir Harry Platt and Prof. E. F. Finch, said in her reply, that in the celebration of the college's anniversary there was a twofold emphasis—on the past and on the future—and she was glad to think that the future was as rich in promise as the past had been in achievement. She congratulated the college on its anniversary with confidence because the traditions on which its great reputation rested were stronger and more precious than ever and had become a part of our national life.

Sir NORMAN HAWORTH, D.SC., F.R.S., for many years professor of chemistry in the University of Birmingham, where he also held the office of vice-principal, died on March 18. In 1937 he shared the Nobel prize for his work on the chemistry of the carbohydrates and particularly his establishment, with E. L. Hirst, of the structural formula of vitamin C which later made its synthesis and large-scale production possible.

THE INDEX and title-page to Vol. II, 1949, which was completed with THE LANCET of Dec. 31, is now in preparation. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam Street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive indexes regularly as published should do so now.

GENERAL PRACTICE IN ENGLAND TODAY

A RECONNAISSANCE

JOSEPH S. COLLINGS *

M.B., B.Sc. (Agr) Sydney

GENERAL medical practice is a unique social phenomenon. The general practitioner enjoys more prestige and wields more power than any other citizen, unless it be the judge on his bench. In a world of ever-increasing management, the powers of even the senior managers are petty compared with the powers of the doctor to influence the physical, psychological, and economic destiny of other people.

But unlike the manager, who exercises his controls over whole groups of society, the doctor exercises his in a microcosm and in relation to individuals; and for this and other reasons he is largely free from the limitations which democratic principles set on the acquisition of power.

General practice is unique in other ways also. For example, it is accepted as being something specific, without anyone knowing what it really is. Neither the teacher responsible for instructing future general practitioners, nor the specialist who supposedly works in continuous association with the G.P., nor for that matter the G.P. himself, can give an adequate definition of general practice. Though generally identified with the last-century concept of "family doctoring," usually it has long ceased to be this. Nevertheless its stability and its reputation rest largely on this identification.

While other branches of medicine have progressed and developed, general practice, instead of developing concurrently, has adapted itself to the changing patterns; and sometimes this adaptation has in fact been regression.

There are no real standards for general practice. What the doctor does, and how he does it, depends almost wholly on his own conscience.

The conduct of general practice and of the individual practitioner is inextricably interwoven with commercial and emotional considerations, which too often negate the code of medical ethics by which the public are supposedly safeguarded and from which the high reputation of medicine stems. Hence material and moral issues have become inseparable, and it is impossible to discuss general practice without discussing morals, and therefore without moralising. In this report the issues are kept separate as far as possible, but this is not very far.

Section I describes how the observations were made; section II is an account of general practice as I found it; and section III deals with the National Health Service in relation to general practice as I found it. I contrast this with the usual endeavour made to interpret the Act in terms of what general practice is supposed to be or what we might like to think it is.

I know well that many of my deductions rest on subjective impressions rather than objective fact, though I have tried to keep the two apart. Very little statistical evidence is used—principally because little valuable evidence of this kind is available, and secondarily because the major problems of general practice are not soluble in terms of statistics.

My observations have led me to write what is indeed a condemnation of general practice in its present form; but they have also led me to recognise the importance of general practice and the dangers of continuing to pretend that it is something which it is not. Instead of continuing a policy of compensating for its deficiencies, we should admit them honestly and try to correct them at their source. If I do no more than convey this, I shall be satisfied.

I. SCOPE AND METHOD OF STUDY

At the outset I was advised that no accurate picture could be obtained by detailed inquiries in the London area, with its aggregation of teaching hospitals and many other complicating factors peculiar to a city of this size. I therefore decided to work outside London, in regions selected so that a mosaic might be constructed which would present the general picture. Having no knowledge of British geography or economy, I was guided by various advisers who knew the country, and eventually decided on three regions—in the north, the north-west, and the south. For purposes of comparison I also spent some time in Scotland.

Thanks to the willing coöperation of all the doctors approached, I have been able to see their work, both in their surgeries and in the homes of their patients, to become conversant with their difficulties, professional and personal, and to learn a great deal about their individual and collective attitudes to the new service.

Though others were visited, I have studied in some detail the work of 55 English practices, operated by 104 doctors. These 55 may be classified as:

Industrial	16
Urban-residential	17
Rural	22

The 16 industrial practices can be further divided into complete industrial 9 and "mixed" (industrial better-class residential) 7. The 22 rural practices can be divided into rural-town 8 and isolated rural 14. Some 30 of the practices were run by individual practitioners; the rest were partnerships or partner-assistantships with 2–6 doctors working together.

The 55 practices visited varied greatly in size (both number of patients and area) and in history and development.

Of the one-man practices some had full lists (4000) while others ranged down through 3000 and 2000 to less than 1000. Examples of different sizes were seen in all areas, though in the industrial areas only two practices were seen where the doctor's list was less than 2000, and in the rural areas only three where the lists approximated to or exceeded 3500. The partnerships and partner-assistantships studied covered much the same wide range of patient numbers, though very few had less than 2000 per partner.

In terms of area covered by a practice and accessibility of patients, conditions ranged from the most compact type of practice, in densely populated urban areas, to remote rural practices with less than 1000 patients living miles apart.

The history and development of the practices showed a similar wide range of variation. Some were over a century old; others had been established before the war but had since been entirely re-established. Many of the industrial practices had had large "panel" and "club" lists since the early days of the old National Health Insurance scheme, and had depended on these for the greater part of the income; but there were various gradations of the panel-private ratio through to completely private practice.

II. THE STATE OF GENERAL PRACTICE

THREE MAIN PATTERNS

General practice is not, as generally assumed, something specific and definable. There are different patterns of practice, and I must distinguish these before describing specific examples.

From the first, I suspected that there were big differences not only in the quality of practice in different areas but also in its nature; but I did not imagine that the differences would be so great or so basic as they proved to be. I thought, rather naïvely, that it was an easy matter to select "good," "average," and "bad" practitioners, and to identify the "good" doctor with good practice or the "bad" doctor with bad practice. I supposed that the "good" doctor would practise well in spite of the social environment in which he worked; but this assumption likewise proved to be false.

The three main patterns of general practice are set by the social environment. They are:

1. General practice in urban industrial areas. (Henceforth called industrial practice.)
2. General practice in better-class urban residential areas. (Henceforth called urban-residential practice.)
3. General practice in rural areas. (Henceforth called rural practice.)

Industrial Practice

Industrial practice has departed a very long way from the ideal of family doctoring. The facilities for medical work are almost always unsatisfactory.

SURGERIES

Consider first the surgeries—the buildings which serve as the doctors' workshops. These are usually located in what was once a shop, or a residence above a shop, or in the downstairs rooms of a house tenanted by some person who takes care of the surgery or occasionally by the doctor himself.

The adaptation of shop or house to doctor's surgery is usually very elementary. As a rule two adjacent rooms serve as waiting and consulting rooms, and where dispensing is undertaken a third room may be set aside for this purpose. That is the basic plan, and there is very little variation from it. Where two or more doctors are working together, there may be two or even three consulting-rooms adjacent to a common waiting-room. The size and plan of the original premises largely determine any other differences between surgeries in industrial areas. I did not see a single industrial surgery which was built for its purpose.

In most cases the waiting-rooms are too small, cold, and generally inhospitable. In peak hours in big practices it is usual to see patients standing, waiting their turn to consult the doctor, and it is not uncommon to see them standing in the garden, where there is one, or queueing in the street where there is not. The comfort of patients and the needs of the sick have certainly not determined the nature of the industrial-practice type of waiting-room.

Consulting-rooms vary greatly in size and furnishings, but are generally comparable from a functional standpoint. Everything is done in this one all-purpose room. The patient is interrogated and the history taken; if he is to be examined he removes such clothing as is necessary (or is convenient) and either hangs it on a hook or piles it on the chair on which he was previously sitting (very rarely a screen is provided, behind which he can change in relative comfort with minimum embarrassment, and very very rarely there may be a changing-room, though I have not myself seen one in an industrial practice); and then the examination is made, sometimes including the collection of a specimen of urine, which is tested at a sink in the same room. It is indeed an all-purpose room.

Quite often the consulting-room is far from soundproof and the most intimate details of a consultation can be distinctly heard in the waiting-room beside it.

The equipment contained in these consulting-rooms also varies considerably. In the sample of practices studied, the range was from satisfactory to dangerously poor—with too many approaching this last category. If we set the basic "heavy" equipment at desk, chairs, examining couch, filing cabinet, instrument cupboard, steriliser, and wash-basin with hot and cold water, and take this as a minimum level of essential heavy equipment for satisfactory practice, we immediately have to classify many industrial practices as unsatisfactory. In several of the surgeries I visited there were no examining couches; in many there were no filing cabinets, and such records as were kept lay around the room either loose or in boxes; in one there was a chair for the doctor only (the patient remained standing throughout consultation and examination); in some a saucepan on a gas-ring served as steriliser; frequently I observed that instruments were kept in odd drawers, or on a table, window-ledge, or mantelpiece, exposed to the atmosphere; and sometimes the doctor had to walk to another part of the premises to wash his hands.

I noted a similar range in the instruments of diagnosis and therapy with which these surgeries were provided. Always obvious were stethoscope, thermometer, tongue-depressor (sometimes of the old bone type, standing in a jar of "antiseptic"), sphygmomanometer, watch, syringes, and needles. Apart from these indispensable articles of practice, there was usually an ophthalmoscope, an auriscope set, and a variety of instruments of varying vintage and type. Proctoscope and vaginal specula were usually in evidence, although frequently there was also abundant evidence of their long disuse. Besides these, a variety of other instruments, antique or sometimes relatively modern, were often to be seen lying around as mementos of past interest in various aspects of medical work.

I have laboured these points of detail somewhat, because it is necessary to recognise the unsatisfactory nature of the doctor's workshop in an average industrial practice; for this factor in itself sets a limit to the scope and quality of his work, to the treatment his patients receive, and to improvement of the situation. Few skilled craftsmen, be they plumbers, butchers, or motor mechanics, would be prepared to work under conditions or with equipment as bad (comparably) as that tolerated by many doctors working in industrial practices.

But even more important than these material conditions is what goes on inside the surgeries and what use is made of the resources they possess.

EXAMINING THE PATIENT

The frequency with which the examining couch is used is a good index of the nature of medical practice under these conditions. I noticed on some occasions that a perfectly serviceable couch was piled with boxes and bottles; the adherence of these articles to the leather cover showed that they had occupied this position for some time. Often I have sat on a doctor's examining couch throughout a consulting hour; and, though many patients gave histories and presented symptoms which indicated the need for thorough examination, they left without any attempt being made to examine them or any arrangements being made for a future examination.

I particularly noted cases where, in my opinion, the history suggested an urgent need for rectal or vaginal examination; and I had listed over forty such cases

Each practice was reviewed in respect of three factors which jointly seem to determine the nature, scope, and quality of medical care :

1. The doctor.
2. The doctor's working environment :
    - (a) Surgery.
    - (b) Equipment.
    - (c) Patient load.
    - (d) Ancillary facilities.
3. The general social environment.

Of these, nos. 2 and 3 lend themselves to objective evaluation. No. 1, the doctor, is much more intangible ; but being undoubtedly the most important single unit in the whole field of medical care, he must be discussed with whatever objectivity is possible.

METHOD OF STUDY

My observations were made by " sitting in on " each practice—a term which requires careful explanation because the validity of these observations, and of some of the conclusions reached, depends on the technique adopted.

In retrospect, " sitting in on " a practice connotes to me a very wide range of behaviour ; everything, in fact, from sitting quietly in a corner trying to efface myself, while the doctor in an embarrassed and artificial way attempted to conduct his consultations, to a nearly complete identification with the doctor's work and behaviour. In the latter cases I found I was able to join in examinations, to interrogate patients, and to discuss points at issue without embarrassment to any of the parties concerned. Fortunately, as a rule the situation approximated, at least after a time, to the last-mentioned happy state of affairs. In the few cases where it did not, I have endeavoured to make allowances or write off the evidence obtained.

Similarly the domiciliary work I did with the doctors ranged from sitting in the car outside the patient's residence and discussing the case with the doctor, or being entertained by the relatives in the front parlour while he had his consultation in the bedroom upstairs, to complete and uninhibited participation in the consultation and examination. Here again the last-mentioned circumstances usually prevailed, and full allowances have been made where they did not.

The time spent " sitting in on " the work of a practice varied from one to four or five days. It depended sometimes on advance arrangements made through a third party, but more often on a personal estimate of the value of the practice as a source of relevant information.

SELECTION OF PRACTICES

The selection of practices and practitioners to be seen was as much beyond my control as the selection of geographical areas in which to work. It was obviously not feasible to take a completely random sample, and precautions had to be taken against the selection of a whole group of " good men." Different people did the selecting in different areas. In most areas a number of people helped to make the selection ; they were asked to select some " good," some " fair," and some " bad " practices. Those usually consulted were regional medical officers who had experience of " refereeing " in the area ; consultants who knew, sometimes personally, always by repute, the practitioners in the area ; local-authority medical officers ; and in some parts of Scotland the chairman and secretary of the local medical committees. Sometimes it was possible to choose the common factors from the lists suggested by two or three people ; sometimes the choice depended partly on which practitioners were available.

The selection among the rural practitioners in the southern region was much more random. It was made by one person, who knew most of those selected by name only. They were chosen largely on geographical situation and not on reputation. In north-west Scotland particular areas were selected and all the practitioners in them were visited.

Occasionally I was passed on from one practitioner to another ; but generally I tried to avoid this. Once I asked to see the work of a particular " group " practice. Always I was introduced to the practice concerned by a disinterested third party who was kind enough to undertake this task.

I am well satisfied that, by this diverse means of sampling, a fair and representative sample of general practice under the various environmental conditions was obtained.

In the northern and north-western regions, before any approach was made to the question of general practice, I sought information from people working for regional hospital boards, executive councils, and local authorities. In the southern region, as a rough control to any bias which might result from this sequence of activity, the general practitioners were visited before I consulted the authorities.

HOSPITALS AND GENERAL PRACTICE

Originally it was proposed that, after reviewing the work of a number of practices in a given area, observations should be made in the outpatient department of the hospitals fed by these practices. It was never intended to follow up particular cases, but to see whether the outpatient work would provide some sort of index of what was happening in a particular type of practice. It was also hoped that some statistical data might be obtained—e.g., the volume and nature of outpatient work before and after July 5, 1948—which would throw light on trends in general practice since the introduction of the service.

In some places it proved possible to do such a " follow through " ; in others, either because the practices fed too many hospitals or because the hospitals were too far away, I could not make any real correlation between the work of the practices and of the outpatient department. However, in every instance I visited some hospitals in or beside the area of study and considered what was happening in the outpatient department.

THE ACT AND THE PROBLEM

When the study began, the National Health Service had been in operation less than six months, and I recognised that it was very early to start assessing its effects on general practice. I also recognised that many of the initial difficulties, often described as " teething troubles," could obscure or complicate the picture. I have therefore tried to separate the " teething " problems from the more formidable long-term problems, and at this early stage I have concerned myself with general trends in the pattern of medical care rather than with the difficulties facing individual practitioners.

It soon became obvious that many problems which had existed for years, and were inherent in general practice as we know it, were being interpreted as results of the new National Health Service. This was very serious because it was preventing clear thought on important issues. Accordingly I decided to attempt first an assessment of general practice at this point of time, out of relation to the new Act, and secondly an interpretation of the actual and possible effects of the Act upon it.

Straight away, some very elementary questions presented. What constitutes general practice *today* ? What does the general practitioner do ? How does he do it ? What criteria have we for judging the quality of general practice ? How does general practice integrate with other medical services—hospital, specialist, and preventive ? To these and other apparently simple yet fundamental questions there are no simple ready-made answers. To some there are just no answers.

I shall begin, then, with a general account of what was seen in the practices studied.

II. THE STATE OF GENERAL PRACTICE

THREE MAIN PATTERNS

General practice is not, as generally assumed, something specific and definable. There are different patterns of practice, and I must distinguish these before describing specific examples.

From the first, I suspected that there were big differences not only in the quality of practice in different areas but also in its nature; but I did not imagine that the differences would be so great or so basic as they proved to be. I thought, rather naïvely, that it was an easy matter to select "good," "average," and "bad" practitioners, and to identify the "good" doctor with good practice or the "bad" doctor with bad practice. I supposed that the "good" doctor would practise well in spite of the social environment in which he worked; but this assumption likewise proved to be false.

The three main patterns of general practice are set by the social environment. They are:

1. General practice in urban industrial areas. (Henceforth called industrial practice.)
2. General practice in better-class urban residential areas. (Henceforth called urban-residential practice.)
3. General practice in rural areas. (Henceforth called rural practice.)

Industrial Practice

Industrial practice has departed a very long way from the ideal of family doctoring. The facilities for medical work are almost always unsatisfactory.

SURGERIES

Consider first the surgeries—the buildings which serve as the doctors' workshops. These are usually located in what was once a shop, or a residence above a shop, or in the downstairs rooms of a house tenanted by some person who takes care of the surgery or occasionally by the doctor himself.

The adaptation of shop or house to doctor's surgery is usually very elementary. As a rule two adjacent rooms serve as waiting and consulting rooms, and where dispensing is undertaken a third room may be set aside for this purpose. That is the basic plan, and there is very little variation from it. Where two or more doctors are working together, there may be two or even three consulting-rooms adjacent to a common waiting-room. The size and plan of the original premises largely determine any other differences between surgeries in industrial areas. I did not see a single industrial surgery which was built for its purpose.

In most cases the waiting-rooms are too small, cold, and generally inhospitable. In peak hours in big practices it is usual to see patients standing, waiting their turn to consult the doctor, and it is not uncommon to see them standing in the garden, where there is one, or queueing in the street where there is not. The comfort of patients and the needs of the sick have certainly not determined the nature of the industrial-practice type of waiting-room.

Consulting-rooms vary greatly in size and furnishings, but are generally comparable from a functional standpoint. Everything is done in this one all-purpose room. The patient is interrogated and the history taken; if he is to be examined he removes such clothing as is necessary (or is convenient) and either hangs it on a hook or piles it on the chair on which he was previously sitting (very rarely a screen is provided, behind which he can change in relative comfort with minimum embarrassment, and very very rarely there may be a changing-room, though I have not myself seen one in an industrial practice); and then the examination is made, sometimes including the collection of a specimen of urine, which is tested at a sink in the same room. It is indeed an all-purpose room.

Quite often the consulting-room is far from soundproof and the most intimate details of a consultation can be distinctly heard in the waiting-room beside it.

The equipment contained in these consulting-rooms also varies considerably. In the sample of practices studied, the range was from satisfactory to dangerously poor—with too many approaching this last category. If we set the basic "heavy" equipment at desk, chairs, examining couch, filing cabinet, instrument cupboard, steriliser, and wash-basin with hot and cold water, and take this as a minimum level of essential heavy equipment for satisfactory practice, we immediately have to classify many industrial practices as unsatisfactory. In several of the surgeries I visited there were no examining couches; in many there were no filing cabinets, and such records as were kept lay around the room either loose or in boxes; in one there was a chair for the doctor only (the patient remained standing throughout consultation and examination); in some a saucepan on a gas-ring served as steriliser; frequently I observed that instruments were kept in odd drawers, or on a table, window-ledge, or mantelpiece, exposed to the atmosphere; and sometimes the doctor had to walk to another part of the premises to wash his hands.

I noted a similar range in the instruments of diagnosis and therapy with which these surgeries were provided. Always obvious were stethoscope, thermometer, tongue-depressor (sometimes of the old bone type, standing in a jar of "antiseptic"), sphygmomanometer, watch, syringes, and needles. Apart from these indispensable articles of practice, there was usually an ophthalmoscope, an auriscope set, and a variety of instruments of varying vintage and type. Proctoscope and vaginal specula were usually in evidence, although frequently there was also abundant evidence of their long disuse. Besides these, a variety of other instruments, antique or sometimes relatively modern, were often to be seen lying around as mementos of past interest in various aspects of medical work.

I have laboured these points of detail somewhat, because it is necessary to recognise the unsatisfactory nature of the doctor's workshop in an average industrial practice; for this factor in itself sets a limit to the scope and quality of his work, to the treatment his patients receive, and to improvement of the situation. Few skilled craftsmen, be they plumbers, butchers, or motor mechanics, would be prepared to work under conditions or with equipment as bad (comparably) as that tolerated by many doctors working in industrial practices.

But even more important than these material conditions is what goes on inside the surgeries and what use is made of the resources they possess.

EXAMINING THE PATIENT

The frequency with which the examining couch is used is a good index of the nature of medical practice under these conditions. I noticed on some occasions that a perfectly serviceable couch was piled with boxes and bottles; the adherence of these articles to the leather cover showed that they had occupied this position for some time. Often I have sat on a doctor's examining couch throughout a consulting hour; and, though many patients gave histories and presented symptoms which indicated the need for thorough examination, they left without any attempt being made to examine them or any arrangements being made for a future examination.

I particularly noted cases where, in my opinion, the history suggested an urgent need for rectal or vaginal examination; and I had listed over forty such cases before I saw a general practitioner pull on a rubber glove and make the examination, or arrange with the patient to do so at a later date. A small proportion of these people were referred to hospital outpatient departments, on the strength of their history alone; but the majority received reassurance and local symptomatic treatment.

In fact, under the prevailing conditions of industrial practice, anything approaching a general or complete examination is out of the question; "examinations" are usually confined to the offending organ and even then are cursory. Certain routine procedures are followed, sometimes almost religiously: throats and tongues are looked at, pulse-rates and temperatures are taken, blood-pressures are recorded on indication, and chests are "listened to," either at the patient's request or for some specific reason. (The process of "listening to" must not be confused with a chest examination: it consists merely in applying the stethoscope to some area readily exposed by unbuttoning a shirt or pulling down an undergarment.) On urgent indication an abdomen may be palpated: I have often seen this done with the patient standing, and I have rarely seen what could be termed a thorough abdominal examination made in an industrial practice.

Once or twice I have seen a doctor, working under these conditions, take a blood sample to send to the laboratory for examination; but as a rule, when such an investigation is thought necessary, the patient is sent in person to the hospital, without consideration for his convenience or sensitivity.

EFFECTS OF ENVIRONMENT

One could go on listing the shortcomings of general practice in industrial areas; but it is neither my purpose nor my desire to defame the overworked and often conscientious doctor who has to suffer the indignities of this way of working.

Where these shortcomings are admitted, people are apt to attribute most of them to the volume of work which the industrial practitioner has to handle. This provides a convenient rationalisation of an otherwise embarrassing situation.

There is no doubt that the volume of work *is* too great, but this is merely a secondary factor. If the doctors' surgeries were better from a functional point of view; if they were equipped at least to some minimum standard; if a little order were brought into the chaos which characterises the organisation of the average practice (e.g., by employing clerical assistants); and if the work of the industrial practitioner were coördinated with that of other medical agencies—then the same volume of work could be handled at a much higher level and with due regard to the safety and comfort of the patient. (As I shall show later, the average industrial practitioner, though he works in close proximity to the great urban medical centres, is more isolated from the benefits these could bestow on him than is his colleague working out in the countryside.)

I found that the working environment of general practitioners in industrial areas was so limiting that their individual capacity as doctors counted for very little. In the circumstances prevailing, the most essential qualification for the industrial G.P., from the standpoint of public safety, is ability as a snap diagnostician—an ability to reach an accurate diagnosis on a minimum of evidence, objective or subjective. The skill attained in this type of diagnosis is sometimes really remarkable, but it very seldom bears any relation to our accepted ideas of "quality" as assessed by academic qualifications or conventional clinical experience. Some of the doctors with least to show in qualifications or hospital experience proved to be the best snap diagnosticians, and therefore the best and safest industrial practitioners, whom I met.

These facts have obviously affected the type of doctor who has entered the jungle of medical practice in industrial areas. Broadly speaking, I came across two types, which one might call the mercenaries and the missionaries. Among the latter are men of outstanding character, sincerity, and occasionally medical ability as displayed by qualifications and experience, who have gone into the industrial areas to "do good." Among the former are some who, by our accepted standards, are judged undesirables.

I saw and worked with some of both of these types and formed the opinion that their environment levels them to a degree where, in effectiveness, there is little to choose between them. In fact, the "mercenary" who is a good snap diagnostician may be of greater value than the "missionary" who cannot match him in this. Under the conditions of industrial practice the "good" doctor has little or no opportunity to exercise his humanistic, psychological, or educational function, which we accept as an essential and integral part of general practice.

Thus in industrial areas medical practice has moved far from the last-century concept of family doctoring; it has not progressed in terms of modern scientific knowledge; and it has reached a point where, despite the efforts of the most conscientious individual doctors, it is at the best a very unsatisfactory medical service and at the worst a positive source of public danger. This is no sudden or recent happening, but is the result of long neglect of the important medical and ethical principles to which we so readily pay lip service.

In 1924 Abraham Flexner[1] wrote:

> "Less than half a century ago the office of an able urban practitioner consisted of two rooms, one for waiting and the other for consultation. There was little to indicate which was which beyond the ancient tilting haircloth examining chair, the wash basin, . . . a few simple instruments which, used for all sorts of purposes, were never boiled, two or three vials containing mercury or carbolic acid for local applications, and the mantelpiece strewn with proprietary preparations in dust-covered bottles. Urinalysis was employed—practically no other laboratory procedure. The doctor made up his mind on the basis of symptoms and obvious physical indications. Long experience and natural shrewdness sharpened by necessity carried the best of the old family physicians far . . . inability to penetrate beneath the surface constantly forced the practitioner to guess or fumble."

Flexner's description of medical practice in the last decades of the 19th century is almost a perfect word-picture of general practice as I found it in the industrial areas of England in 1949. This section of general practice indeed provides an example of what Mannheim has defined as "non-contemporaneous contemporaneity."

If, in the process of becoming an anachronism, this branch of medicine had retained the ideals and the human elements of the old concepts of family doctoring we might even be able to defend and applaud what has happened; but it would be dishonest to pretend that it has.

SCOPE OF WORK

To display more fully the pattern of medical practice in industrial areas I must summarise the work done under these conditions.

Diagnosis

With limited time, facilities, and equipment, the doctor attempts to arrive at diagnoses and to refer those patients requiring more skilled attention to a place where such attention can be given. Much of this diagnostic work is empirical and some almost intuitive.

For the most part he deals with people of ages ranging from the late teens to the early sixties—the working section of the community. The school clinics and maternity and child-welfare clinics have relieved him of responsibility for caring, in a comprehensive way, for the school and preschool child, and also for the expectant and nursing mother. While he may attend many patients over sixty years of age, it is more a question of attending than caring for them: the time and the inclination to bring medical skills to bear on the problems of this age-group are sadly lacking.

---

[1] Flexner, A. Medical Education. London, 1925; p. 9.

Therapy

Treatment is even more restricted than diagnosis. Most of it is symptomatic, and nearly all of it is medicinal; for there is neither time nor opportunity for physical therapy or psychotherapy.

Without access to hospitals, doctors working under these conditions naturally do no major surgery. Most of them do no minor surgery either. It is rare indeed to see a practitioner in an industrial area open an abscess, put in a suture, remove a fingernail, or indeed undertake any procedure requiring sterilisation of instruments.

Midwifery

Before July, 1948, most industrial practitioners had long since yielded all responsibility for midwifery to the midwives and the maternity and child-welfare clinics. The few who continued to dabble in midwifery were mostly considered by midwives and other responsible observers to be a menace, and from what I saw of the antenatal work of some of them I can endorse this opinion.

Minor Laboratory Work

This is almost confined to testing urines for albumin and sugar, and then only on specific indication (e.g., an apparent toxæmia of pregnancy as opposed to routine antenatal test). A microscope is seldom seen among the G.P.'s equipment. Estimations of hæmoglobin and sedimentation-rates, and other simple and useful tests, are seldom done: though, as I said before, the surgery often contains odd pieces of apparatus, the instruments of such tests.

To analyse the doctor's work beyond this point is scarcely possible at present; nor, in my opinion, is it necessary. With a problem so crude, greater detail is of little but academic interest. Time-studies, age, sex, pathological, or other breakdowns of the doctor's work are out of the question with medical records either non-existent or so superficial as to be valueless for this purpose.

The important point is that this form of practice constitutes the pattern for most industrial areas, and that the pattern is accepted by doctor and patient alike. It is far away from the ideal of family doctoring on the one hand, and of modern scientific medical practice on the other; yet it is still wilfully identified with both of these.

Rural Practice

Rural practice is in many ways the antithesis of industrial practice; and in judging the quality of rural medical care we have to employ different criteria.

SURGERIES

Though built to the same pattern, and functionally little different, the country surgeries I visited were much pleasanter places than their town equivalents. For the most part they were better equipped—though I did see two without an examining couch and others where this was merely an adornment. Moreover, functional imperfections in a rural surgery are less important than the same imperfections in an urban one, where time and efficiency are paramount factors in the quality of the service which can be offered. In fact, premises which would be deplorable under urban conditions may pass as interesting and quaint examples of last-century architecture and custom when they are found, say, in a small south-country village. I saw some surgeries which had served successive doctors for over a century, and they served well enough today, though they might not satisfy an efficiency expert.

In a rural town the doctor's surgery must be considered in association with the cottage hospital, as a combined unit, the one supplementing the other. In isolated rural practice, on the other hand, the doctor's surgery assumes a new importance; it needs to be well enough equipped to enable him to meet responsibilities and demands which his colleagues nearer centres of civilisation can pass on at a moment's notice. At least by existing standards, the rural-town cottage-hospital combination is nearly always satisfactory (if we exclude the requirements for major operations): but the surgery of the isolated country practitioner is as often unsatisfactory in the extreme, and places him, and accordingly his patients, at a serious disadvantage.

I saw this latter point illustrated many times. For example, I have seen a patient sent many miles when a microscopical examination of urine might have confirmed a diagnosis of pyelitis rather than one of appendicitis; but there was no microscope. Similarly the absence of a microscope necessitates more empirical diagnosis, and consequent empirical therapy, than is desirable, and causes unnecessary inconvenience, expense, and sometimes danger to patients who have to travel to the nearest hospital. The microscope, indeed, is almost indispensable to the isolated country practitioner, yet is seldom included in his equipment; and other simple things, such as hæmoglobinometers and blood-sedimentation apparatus, are very uncommon. It is, of course, debatable how much the individual practitioner should attempt on his own; but it is surely fair to expect him to do whatever he is able to do for the convenience and benefit of his patients.

I saw some isolated rural practices which were quite as badly equipped as the worst industrial practices I visited. But in spite of the poorness of these surgeries and equipment, and the question of how a serious emergency would be met in them, it is impossible to assess the quality of such a practice on the same basis as would be appropriate for an urban practice. Not only has the country doctor the time to examine his patients but he also has the time to know them intimately: and his judgment is usually based on a greater knowledge and a deeper consideration, both of the person and of the ailment, than his city colleagues can compass.

This is not to say that he could not do much better work under better conditions, but rather that the good country doctor can and does overcome the obstacles of bad environment, in terms of surgery and equipment, in a way impossible for the city doctor. Furthermore, the country G.P. is fulfilling a function, in the psychological as distinct from the organic field, in a real way which again is impossible for the city doctor. A rural practitioner, who may only be "fair" so far as organic medicine is concerned, may still qualify as an excellent family doctor.

STANDARD OF WORK

Under the conditions prevailing in rural practice, the quality of the medical care is governed chiefly by the quality of the doctor himself. This is very difficult to assess but not difficult to recognise.

During my study, I met and worked with some men who could be graded, on an absolute standard, as first-class. They were good clinicians, good technicians, and fine humanists. Of the others, the majority, while belonging to the third category, rapidly fell away through fair to bad in the first and the second. Yet, as I have just said, this does not necessarily mean that they were not "good" doctors.

This again brings up the question of criteria. In seeking a sample of "good," "average," and "bad" practices, I found it hard to get people to nominate "bad" doctors in rural areas. There is a tendency to regard the country doctor as "good," if for no other reason than the urge to identify him with our concept of the ideal—the real family doctor. However, in the south, where a more or less random sample was taken, before I saw a general practitioner pull on a rubber glove and make the examination, or arrange with the patient to do so at a later date. A small proportion of these people were referred to hospital outpatient departments, on the strength of their history alone; but the majority received reassurance and local symptomatic treatment.

In fact, under the prevailing conditions of industrial practice, anything approaching a general or complete examination is out of the question; "examinations" are usually confined to the offending organ and even then are cursory. Certain routine procedures are followed, sometimes almost religiously: throats and tongues are looked at, pulse-rates and temperatures are taken, blood-pressures are recorded on indication, and chests are "listened to," either at the patient's request or for some specific reason. (The process of "listening to" must not be confused with a chest examination: it consists merely in applying the stethoscope to some area readily exposed by unbuttoning a shirt or pulling down an undergarment.) On urgent indication an abdomen may be palpated: I have often seen this done with the patient standing, and I have rarely seen what could be termed a thorough abdominal examination made in an industrial practice.

Once or twice I have seen a doctor, working under these conditions, take a blood sample to send to the laboratory for examination; but as a rule, when such an investigation is thought necessary, the patient is sent in person to the hospital, without consideration for his convenience or sensitivity.

EFFECTS OF ENVIRONMENT

One could go on listing the shortcomings of general practice in industrial areas; but it is neither my purpose nor my desire to defame the overworked and often conscientious doctor who has to suffer the indignities of this way of working.

Where these shortcomings are admitted, people are apt to attribute most of them to the volume of work which the industrial practitioner has to handle. This provides a convenient rationalisation of an otherwise embarrassing situation.

There is no doubt that the volume of work *is* too great, but this is merely a secondary factor. If the doctors' surgeries were better from a functional point of view; if they were equipped at least to some minimum standard; if a little order were brought into the chaos which characterises the organisation of the average practice (e.g., by employing clerical assistants); and if the work of the industrial practitioner were coördinated with that of other medical agencies—then the same volume of work could be handled at a much higher level and with due regard to the safety and comfort of the patient. (As I shall show later, the average industrial practitioner, though he works in close proximity to the great urban medical centres, is more isolated from the benefits these could bestow on him than is his colleague working out in the countryside.)

I found that the working environment of general practitioners in industrial areas was so limiting that their individual capacity as doctors counted for very little. In the circumstances prevailing, the most essential qualification for the industrial G.P., from the standpoint of public safety, is ability as a snap diagnostician—an ability to reach an accurate diagnosis on a minimum of evidence, objective or subjective. The skill attained in this type of diagnosis is sometimes really remarkable, but it very seldom bears any relation to our accepted ideas of "quality" as assessed by academic qualifications or conventional clinical experience. Some of the doctors with least to show in qualifications or hospital experience proved to be the best snap diagnosticians, and therefore the best and safest industrial practitioners, whom I met.

These facts have obviously affected the type of doctor who has entered the jungle of medical practice in industrial areas. Broadly speaking, I came across two types, which one might call the mercenaries and the missionaries. Among the latter are men of outstanding character, sincerity, and occasionally medical ability as displayed by qualifications and experience, who have gone into the industrial areas to "do good." Among the former are some who, by our accepted standards, are judged undesirables.

I saw and worked with some of both of these types and formed the opinion that their environment levels them to a degree where, in effectiveness, there is little to choose between them. In fact, the "mercenary" who is a good snap diagnostician may be of greater value than the "missionary" who cannot match him in this. Under the conditions of industrial practice the "good" doctor has little or no opportunity to exercise his humanistic, psychological, or educational function, which we accept as an essential and integral part of general practice.

Thus in industrial areas medical practice has moved far from the last-century concept of family doctoring; it has not progressed in terms of modern scientific knowledge; and it has reached a point where, despite the efforts of the most conscientious individual doctors, it is at the best a very unsatisfactory medical service and at the worst a positive source of public danger. This is no sudden or recent happening, but is the result of long neglect of the important medical and ethical principles to which we so readily pay lip service.

In 1924 Abraham Flexner[1] wrote:

> "Less than half a century ago the office of an able urban practitioner consisted of two rooms, one for waiting and the other for consultation. There was little to indicate which was which beyond the ancient tilting haircloth examining chair, the wash basin, . . . a few simple instruments which, used for all sorts of purposes, were never boiled, two or three vials containing mercury or carbolic acid for local applications, and the mantelpiece strewn with proprietary preparations in dust-covered bottles. Urinalysis was employed—practically no other laboratory procedure. The doctor made up his mind on the basis of symptoms and obvious physical indications. Long experience and natural shrewdness sharpened by necessity carried the best of the old family physicians far . . . inability to penetrate beneath the surface constantly forced the practitioner to guess or fumble."

Flexner's description of medical practice in the last decades of the 19th century is almost a perfect word-picture of general practice as I found it in the industrial areas of England in 1949. This section of general practice indeed provides an example of what Mannheim has defined as "non-contemporaneous contemporaneity."

If, in the process of becoming an anachronism, this branch of medicine had retained the ideals and the human elements of the old concepts of family doctoring we might even be able to defend and applaud what has happened; but it would be dishonest to pretend that it has.

SCOPE OF WORK

To display more fully the pattern of medical practice in industrial areas I must summarise the work done under these conditions.

Diagnosis

With limited time, facilities, and equipment, the doctor attempts to arrive at diagnoses and to refer those patients requiring more skilled attention to a place where such attention can be given. Much of this diagnostic work is empirical and some almost intuitive.

For the most part he deals with people of ages ranging from the late teens to the early sixties—the working section of the community. The school clinics and maternity and child-welfare clinics have relieved him of responsibility for caring, in a comprehensive way, for the school and preschool child, and also for the expectant

---

1. Flexner, A. Medical Education. London, 1925; p. 9.

The range of work undertaken in different practices is wide; but it seems clear that the rural practitioner on the one hand still approximates to the ideal of the family doctor, and, on the other, at least aspires to meet the demands of modern science and procedure. It must be said, however, that over a considerable section of rural practice these aspirations do not take us very far, and that, compared with his colleagues in the industrial areas, the rural practitioner must accept a greater measure of responsibility for his own shortcomings. Conversely he is entitled to due respect for his achievements.

In the final analysis present-day rural practice remains an anachronism, though one which has retained many of the virtues of the past.

Urban-residential Practice

Urban-residential practice is dealt with out of turn because, though it is intermediate between the extremes of industrial and rural practice, it is less easily defined in terms of scope or quality. "Good" practices of this type resemble the best of rural practice, and "bad" practices the kind of thing so common in industrial areas; yet urban-residential practice has certain features which establish a distinctive pattern.

Some of these are superficial—no more than a veneer of sophistication on the crudities of industrial practice. Others are more basic, and quite characteristic. The superficial differences are perhaps the more obvious.

SURGERIES

Take the surgeries, for example. Most of them follow the two-room design of the industrial type, but there is a world of difference in the furnishings, style, and regard for patients' comfort and tastes. A large proportion of these surgeries have been "made over" from the front rooms of a family home in much the same way as the surgeries of the industrial practitioner have been adapted from an erstwhile shop or residence. But I have been in surgeries built by the doctor for the specific purpose, and have been impressed by the fact that they too have usually followed the two-room (waiting-room and consulting-room) pattern. Evidently the belief that two rooms are all that is necessary to run a general practice is firmly rooted in the medical mind. Twice I have met doctors who at some stage were adventurous enough to build themselves three-room surgeries, but who, over the years, have reverted to type and are now working in two and using the third room for storage. There are, of course, exceptions to this rule, and some doctors have built surgeries which are excellent from the functional point of view; but these are very definitely exceptions. One cannot suppose that the difference in capital outlay required to construct a good as opposed to an unsatisfactory surgery has been the determining factor. The designs must be primarily the result of an unquestioning acceptance of the traditions of the last century and a failure to think about general practice in contemporary and constructive terms.

The waiting-room in an urban-residential practice is in striking contrast to the waiting-rooms in industrial practice; for the patient with more cultivated taste expects attention to the niceties. Similarly the consulting-room is of a more refined type: the basic "heavy" equipment is more attractive in appearance; instrument cupboards, containing sometimes quite an extraordinary range of instruments, are usually in evidence; and equipment for filing records is often an asset to the furnishings. Yet these differences in the two types of practice, impressive though they look, are actually very superficial and often make very little difference to the quality of care offered. Thus, despite the advantage of good filing equipment, I have noticed little significant difference in record-keeping in the two types of practice. Again, except where in absolute terms he qualifies as a "good" doctor, I have seldom observed that the more abundant equipment carried by the urban-residential practitioner has been put to much significant use. I could cite numerous cases of patients presenting histories indicating the need for ophthalmoscopic examination who have left the surgery without any such examination, though an excellent and expensive ophthalmoscope lay within reach of the doctor; and in some of the cases already mentioned, where rectal or vaginal examination seemed desirable, the patient was standing within feet of a selection of very fine specula, never called into service.

There is absolutely no cynicism about these remarks. It is perfectly natural that the demand for well-appointed waiting and consulting rooms should lead to their being supplied. But it is important that we should avoid the assumption that if a surgery is attractively appointed it is functionally good, and the further assumption that an apparently good surgery means good medical care. In the course of my study I continually found these assumptions in the minds of people from whom a more objective opinion might have been expected.

I would say that though most of the urban-residential surgeries I visited were better equipped and better appointed, they were functionally almost as unsatisfactory as their industrial-area equivalents.

NATURE OF THE WORK

In urban-residential areas the capacity of the individual doctor has more free play than in industrial areas, but usually less than in the countryside. The few doctors left with hospital privileges have much the same scope of work as the rural practitioner, and may know their patients in much the same way. The majority, however, work under greater pressure and lack these hospital privileges, and on the average they represent a rather unhappy compromise between the two extremes.

The number of patients handled by the urban-residential practitioner is very variable, and an extra 500–600 can reduce the standard of his work much more appreciably than a similar numerical increase will reduce the standard of work of the industrial practitioner.

As local-authority services do not operate to nearly the same extent in these better residential environments, the general practitioner should carry a greater responsibility, for example, in the care of mother and child. But I saw little to suggest that he does so; and I can only conclude that in these areas the work which is done elsewhere by the local-authority clinics is usually not done satisfactorily or not done at all.

Compared with the industrial doctor, the urban-residential doctor spends a considerably longer time on each patient. But on the whole there seems to be little difference in the time spent on physical examination. There are, of course, exceptions.

The scope of the urban-residential practitioner's work has possibly undergone more change of late years than that of either of the other two groups; and for this if no other reason it is harder to establish a pattern. The doctor's individual capacity is still reflected in his work, but to an ever-decreasing extent. He has more social contact with his consultant colleagues than doctors have in either of the other environments, but probably no more professional contact.

Urban-residential practice is certainly the most difficult to assess. It represents the transition from the ideal of family practice to the "casualty-clearing station" type of practice seen in industrial areas. While it obviously does not meet all the requirements of medical care, it is more or less immune from the contrary criticisms which can be directed against rural practice on the one hand and industrial practice on the other.

I was better able to make an unbiased classification of the doctors I visited.

From the strictly technical standpoint many of them were "bad": though they all had a working knowledge of the use of such modern preparations as penicillin and the sulpha drugs, their knowledge on the whole was out of date. But if the skills they exercised were very limited in any one field, they embraced many fields; and so long as the man was a good and conscientious observer he was usually a "good" doctor in the circumstances in which he practised.

However, I worked with some who, though regarded as "good" by both the profession and the public, were in fact "bad" in absolute terms. All the men I would put in this category were well qualified from reputable medical schools; most of them had been in practice for many years and were regarded, more or less, as "the squire." Their chief fault, as I saw it, was that they were not good or thorough observers of either organic or psychological problems, and took no pains to check their impressions and opinions by objective investigation. They worked to a routine and within limits that had long since dulled their curiosity and their sensitivity. For example:

> Taking a surgery with a practitioner who enjoyed a high reputation both professionally and publicly, I saw a man come in who was icteric and almost emaciated. The object of his visit was to get a bottle of medicine for his wife. I asked, after he had gone, what was the cause of his strange colour and condition. The answer was "Oh, I don't know, there's nothing much wrong with him; he's been like that for three years."
>
> At another time a doctor took me to see a case of which he was particularly proud—an old man of sixty-five with a dry gangrenous leg, which had been preserved by keeping the patient in bed for twelve months since the sudden onset of the condition, still undiagnosed. The doctor visited regularly to "dress" the dead appendage, and his attitude was that here was an old man comfortable enough in bed and not requiring any active therapy.

In the same region I spent some days with a young doctor who had only a small number of patients but who tried to give a service satisfying his own high standards. As this practice was very isolated and poorly served by consultant and laboratory services, he had built his own little laboratory and fitted it with apparatus which enabled him to do many things not normally considered part of general practice. He did a lot of microscopy and such tests as blood-sugars, blood-ureas, and clotting-times; also he had a portable electrocardiograph and other equipment which enabled him to do a most comprehensive job of diagnosis and therapy.

While I am not saying that this should be the model of general practice, or that this man was not taking on too much, I must emphasise that as an individual, looking after 1300 patients, he was exercising a wider range of skills than any other G.P. I have seen, and in my opinion exercising them within the limits of safety. Beyond dispute he was offering a quality of service far above anything his colleagues could offer. The point I want to make is that these colleagues, who had larger practices, enjoyed unassailable reputations, and had no cause for jealousy, regarded this doctor as crazy. In their unqualified opinions he was mad—merely because he endeavoured to exercise to the limit the skills of which he was capable in the interests of his patients. Because of his small practice, and in spite of his excellent work, he was suffering serious financial embarrassment, and has probably by now been forced out of his practice and into some more lucrative field.

I also came across a "group" practice, which had been operating for about eighteen years in a small village. It was run by a group of four—three partners and an assistant. Their surgery was the first and only one I saw which had been carefully planned and built as a separate working unit, and, though they would like to improve on the design, it was far better than any other surgery I visited in Great Britain.

In qualifications and experience the doctors working this group were wholly comparable with their neighbours. But, from the point of view of the patient, the service they offered was vastly superior to anything that could be provided by the surrounding doctors. They ran a highly organised group practice, and by virtue of their good organisation alone they had more time to devote to their work and interests. One was particularly interested in surgery and another in obstetrics, but they were all general practitioners in the full meaning of the term. Their records were better than any others I have seen in England (I still would not say that they were good); they employed clerical and nursing assistance; and they did not share the common opinion that the expense of such assistance was unjustified or could not be carried by a practice of moderate size and income. Their whole attitude of mind was different from that of the average doctor; they were constantly trying to improve their equipment and to widen their scope of work, and they were interested in children and old people to a degree not usual in the general practitioner.

THE RURAL PATTERN

Enough has been said to illustrate the two points I want to make at this stage:

1. That the whole pattern of practice in rural areas differs greatly from that in industrial areas.
2. That we must apply different criteria when judging the quality of medical care offered by, or possible within, these two types of practice.

For purposes of contrast I summarise the scope of work undertaken by the rural practitioner:

Diagnosis

Rural practitioners often undertake a high level of diagnostic responsibility, though some of them work in the same empirical way as their industrial colleagues and to about the same elementary level. The difference is that in the country the level usually depends on the doctor's choice and is not imposed by his environment.

With reasonable cottage-hospital facilities the rural practitioner can and often does work to much the same level as the consultant physician, with the added advantage that he knows his patients intimately and often over a long period.

He deals with people of all ages—not primarily with the working section of the community. Nevertheless, for the most part he has the same attitude as his urban colleagues towards the medical problems of his elderly or "chronic" patients.

Therapy

The therapeutic responsibility of the rural practitioner is also wide. He seldom limits himself to medicinal treatment. Physical and psychological therapy come well within his terms of reference; minor surgical procedures are almost a daily routine; and, where he has access to a cottage hospital, he commonly undertakes major surgery.

Midwifery

Though the trend for many years has been away from general-practice obstetrics, the country doctor still usually does some of the midwifery of his area. From such observations as I was able to make, the average rural G.P. is no obstetric paragon. However, through his association with mother and child he retains an intimacy and a bond which marks him as a family doctor.

Minor Laboratory Work

Again, the amount of minor laboratory work undertaken by the rural G.P. is determined by his own interest rather than by the circumstances which restrict the man in industrial practice. A still significant proportion of country doctors carry their side-bench work beyond casually testing an odd urine for sugar and albumin. Some do quite advanced laboratory work even within the confines of their own surgery.

The range of work undertaken in different practices is wide; but it seems clear that the rural practitioner on the one hand still approximates to the ideal of the family doctor, and, on the other, at least aspires to meet the demands of modern science and procedure. It must be said, however, that over a considerable section of rural practice these aspirations do not take us very far, and that, compared with his colleagues in the industrial areas, the rural practitioner must accept a greater measure of responsibility for his own shortcomings. Conversely he is entitled to due respect for his achievements.

In the final analysis present-day rural practice remains an anachronism, though one which has retained many of the virtues of the past.

Urban-residential Practice

Urban-residential practice is dealt with out of turn because, though it is intermediate between the extremes of industrial and rural practice, it is less easily defined in terms of scope or quality. "Good" practices of this type resemble the best of rural practice, and "bad" practices the kind of thing so common in industrial areas; yet urban-residential practice has certain features which establish a distinctive pattern.

Some of these are superficial—no more than a veneer of sophistication on the crudities of industrial practice. Others are more basic, and quite characteristic. The superficial differences are perhaps the more obvious.

SURGERIES

Take the surgeries, for example. Most of them follow the two-room design of the industrial type, but there is a world of difference in the furnishings, style, and regard for patients' comfort and tastes. A large proportion of these surgeries have been "made over" from the front rooms of a family home in much the same way as the surgeries of the industrial practitioner have been adapted from an erstwhile shop or residence. But I have been in surgeries built by the doctor for the specific purpose, and have been impressed by the fact that they too have usually followed the two-room (waiting-room and consulting-room) pattern. Evidently the belief that two rooms are all that is necessary to run a general practice is firmly rooted in the medical mind. Twice I have met doctors who at some stage were adventurous enough to build themselves three-room surgeries, but who, over the years, have reverted to type and are now working in two and using the third room for storage. There are, of course, exceptions to this rule, and some doctors have built surgeries which are excellent from the functional point of view; but these are very definitely exceptions. One cannot suppose that the difference in capital outlay required to construct a good as opposed to an unsatisfactory surgery has been the determining factor. The designs must be primarily the result of an unquestioning acceptance of the traditions of the last century and a failure to think about general practice in contemporary and constructive terms.

The waiting-room in an urban-residential practice is in striking contrast to the waiting-rooms in industrial practice; for the patient with more cultivated taste expects attention to the niceties. Similarly the consulting-room is of a more refined type: the basic "heavy" equipment is more attractive in appearance; instrument cupboards, containing sometimes quite an extraordinary range of instruments, are usually in evidence; and equipment for filing records is often an asset to the furnishings. Yet these differences in the two types of practice, impressive though they look, are actually very superficial and often make very little difference to the quality of care offered. Thus, despite the advantage of good filing equipment, I have noticed little significant difference in record-keeping in the two types of practice. Again, except where in absolute terms he qualifies as a "good" doctor, I have seldom observed that the more abundant equipment carried by the urban-residential practitioner has been put to much significant use. I could cite numerous cases of patients presenting histories indicating the need for ophthalmoscopic examination who have left the surgery without any such examination, though an excellent and expensive ophthalmoscope lay within reach of the doctor; and in some of the cases already mentioned, where rectal or vaginal examination seemed desirable, the patient was standing within feet of a selection of very fine specula, never called into service.

There is absolutely no cynicism about these remarks. It is perfectly natural that the demand for well-appointed waiting and consulting rooms should lead to their being supplied. But it is important that we should avoid the assumption that if a surgery is attractively appointed it is functionally good, and the further assumption that an apparently good surgery means good medical care. In the course of my study I continually found these assumptions in the minds of people from whom a more objective opinion might have been expected.

I would say that though most of the urban-residential surgeries I visited were better equipped and better appointed, they were functionally almost as unsatisfactory as their industrial-area equivalents.

NATURE OF THE WORK

In urban-residential areas the capacity of the individual doctor has more free play than in industrial areas, but usually less than in the countryside. The few doctors left with hospital privileges have much the same scope of work as the rural practitioner, and may know their patients in much the same way. The majority, however, work under greater pressure and lack these hospital privileges, and on the average they represent a rather unhappy compromise between the two extremes.

The number of patients handled by the urban-residential practitioner is very variable, and an extra 500–600 can reduce the standard of his work much more appreciably than a similar numerical increase will reduce the standard of work of the industrial practitioner.

As local-authority services do not operate to nearly the same extent in these better residential environments, the general practitioner should carry a greater responsibility, for example, in the care of mother and child. But I saw little to suggest that he does so; and I can only conclude that in these areas the work which is done elsewhere by the local-authority clinics is usually not done satisfactorily or not done at all.

Compared with the industrial doctor, the urban-residential doctor spends a considerably longer time on each patient. But on the whole there seems to be little difference in the time spent on physical examination. There are, of course, exceptions.

The scope of the urban-residential practitioner's work has possibly undergone more change of late years than that of either of the other two groups; and for this if no other reason it is harder to establish a pattern. The doctor's individual capacity is still reflected in his work, but to an ever-decreasing extent. He has more social contact with his consultant colleagues than doctors have in either of the other environments, ~~but~~ probably no more professional contact.

Urban-residential practice is certainly the most difficult to assess. It represents the transition from the ideal of family practice to the "casualty-clearing station" type of practice seen in industrial areas. While it obviously does not meet all the requirements of medical care, it is more or less immune from the contrary criticisms which can be directed against rural practice on the one hand and industrial practice on the other.

SPECIFIC EXAMPLES OF GENERAL PRACTICE

I shall now describe a few examples of practice under the various environmental conditions, including one or two which illustrate the effect of differences in the number of patients or the history of the practice.

Industrial Practice

I

Two partners and an assistant. Approximately 10,000 patients on the list. No private patients.

This practice, locally classified as " good," had been established for many years and had always had a large " panel " list under the National Health Insurance Act. The district it served was densely populated, and in area no more than a few square miles; most of the housing was very bad, though some slum clearance had gone on at different times and there were rehousing estates of various dates. The inhabitants were largely engaged in heavy or light industry, the former predominating.

The surgery was on the ground floor of a tenement house and was difficult of access for many patients. It comprised a very small waiting-room, two consulting-rooms, and a dispensary; and, though the site was unsuitable, it was well equipped compared with most of the other industrial surgeries I visited.

The doctors held morning and evening consulting hours six days a week, two of them working simultaneously in the surgery while the third was out on " calls." The consulting " hour " always extended to two or three hours, and they were seeing anything from 30 to 50 patients each during the consulting period. They employed a lady dispenser, who also acted as telephonist and receptionist and undertook some clerical duties.

An attempt was made to keep a file record, but this consisted mainly of a very few brief notes pertaining to the " really serious illnesses," and such letters and reports as came back from the various hospitals to which patients had been referred. A remarkably large proportion of the record cards which I saw coming out of, and going back into, the files bore nothing more than the patient's name, age, and address.

Two of the doctors undertook domiciliary midwifery; between them they totalled about 25 cases a year.

On the occasions I attended the surgery, the waiting-room was packed and sometimes patients were standing in the front grounds. I was informed that this was not a heavy period, there being a relative absence of epidemics. The average length of a consultation was three to five minutes, whether it was a new case or a return visit; a " serious case " or one involving some degree of physical examination would take, perhaps, ten to fifteen minutes.

It is hardly necessary to say that, in such circumstances and working to such a schedule, physical examinations were cursory and were kept to a minimum. Most examinations were made with the patient sitting or standing, and with removal of the least possible amount of clothing. The examining couch was seldom called into use. I never saw vaginal, rectal, or ophthalmoscopic examination attempted, though during my time at this surgery many patients were seen who seemed to me to require one or other of these examinations. In all such cases I asked the doctor and/or the patient whether such an examination had been made at a previous time, and the answer was always No. It must, however, be said that a proportion of these people were sent to hospital for the opinion of a specialist. Indeed in most cases where the brief histories taken, or the examination made, suggested potentially serious organic disease, the patient was referred to an outpatient department. In this particular practice a great number of patients were similarly referred for laboratory and radiological diagnostic tests. Usually all the doctor wanted was the result of the particular test and not another opinion.

These practitioners undertook the antenatal care of their own patients. This was done in a very loose way. Inquiry was made as to how the patient felt; blood-pressures were taken only on some specific indication; samples of urine were brought only occasionally and then examined only if there was some special reason. In the only case of early pregnancy which came in during my stay no attempt was made to make a pelvic or general examination: the patient was told to "*come back in a couple of months to be antenataled " and it was left* at that. The chief purpose of the visit, so far as both patient and doctor were concerned, seemed to be the supply of certificates for the various benefits accorded to the expectant mother. No antenatal records were kept.

The treatment of the numerous children who were brought in during my time in this practice was similar to that of the adults, but on the least suspicion of serious illness they were referred to a pædiatric clinic at the local hospital.

Though this practice had run a dispensary for many years, the " bottle of medicine " mentality was not highly developed, and indiscriminate prescribing seemed to be at a minimum.

It is often very difficult to assess the legitimacy of claims made for sickness benefits and the like, but I formed the impression that these practitioners erred considerably on the side of leniency. The time and effort required to meet the demands of certification did not seem excessive.

I made a considerable number of domiciliary visits with these doctors. It was always a rush to get through the list, and the same factors as led to cursory examination in the surgery operated in home calls also. Except in special circumstances, three or four minutes sufficed for each visit.

In both surgery and domiciliary work a lack of interest in the non-acute cases was conspicuous—particularly with elderly or " chronic " patients. Though these were visited with scrupulous conscientiousness, it was apparently not thought worth bringing medical skills to bear on their problems. In fact, the over-sixties suffering from any condition resulting in long-continued immobilisation were regarded as more or less hopeless cases, worthy of pity and charity but scarcely of serious medical attention.

The many patients seen who presented themselves obviously for psychological and not for organic reasons were treated with hearty reassurance and quick dismissal.

These doctors had no hospital or nursing-home facilities for their own use. They had no visiting rights at the large general or special hospitals. They knew and were on good terms with the consultants of the district, but saw very little of them. They were very hard-working and conscientious, and, as far as one could ascertain from the limited clinical procedures they undertook, they were good clinicians, at least within the limits set by the type of work they were doing. Certainly they were highly skilled at snap diagnosis.

This was very much the picture in all the " good " industrial practices where the conditions of work were similar. The only absolute difference was that in most of them no midwifery was done. The man who, in terms of qualifications and hospital experience, was the best industrial practitioner I saw working under comparable conditions conducted his practice in just the same way. He was one of a partnership of four. In his company, I did a round which took us to 38 houses between 11 A.M. and 4.30 P.M. (with time off for lunch). There is little need to elaborate on the perfunctory nature of the visits or the effects of such a manner of practice on a man of very high clinical ability. This particular partnership was the only industrial practice I visited where there was any significant division of the field of work. One partner had taken responsibility for the "old chronics," which not only reduced the load on his colleagues handling "acute" cases but also greatly benefited the old patients.

Throughout the "good" industrial practices visited, premises and equipment were unsatisfactory; record-keeping, at the best, was not good; antenatal work, where done at all, was casual; and the routine work of diagnosis and therapy was limited by time and circumstance much as in the practice I have described.

II

Four partners and two assistants. Approximately 20,000 patients on the list.

This practice was of fairly long standing, and under the National Health Insurance Act had carried a very large "panel" list. It was in a densely populated area, where light industry predominated and housing conditions were deplorable; whole terraces of houses had been condemned for years, but little in the way of slum clearance had been undertaken. The boundaries of the practice encompassed several square miles, and the total mileage covered by the doctors in the year was large.

The surgery consisted of a small dilapidated waiting-room, three equally small and untidy consulting-rooms, and a kind of cupboard which served as a dispensary (the practice had always done its own dispensing). The consulting-rooms were dirty and ill equipped. There were no examining couches, and no apparent means of sterilising anything; indeed, apart from a few rusty and dusty antique instruments, there was no sign of any sort of equipment. Large stock bottles were standing all over the place, and the desk and floor were littered with papers. Only one of the consulting-rooms was equipped with a hand-basin and hot and cold water.

I made my visit during an afternoon consulting hour, and found a queue of people extending about 200 yards up the street, waiting their turn to see the doctors; they were standing packed in the waiting-room and I had to force an entrance. I was made welcome "to see the procession," given a seat and a cup of tea, and invited to stay "as long as I liked." I was told, not without pride, that "we have seen 500 already today"; and I have no reason to doubt it.

During my stay of an hour and a quarter about 120 more patients came in. They were "seen" by three different doctors, who replaced one another with almost bewildering rapidity. No pretence was made at real examination of any of these patients. An occasional temperature or pulse-rate was taken; four or five times a stethoscope was applied to a point somewhere below the thyroid gland and some such utterance made as "ah, a bit chesty."

The bottle of medicine was the sine-qua-non of this practice. One small child came in requesting "a bottle for the lady over the road." He could give no further information, apart from her name and address, which obviously conveyed nothing to the doctor; but he produced a dirty-looking bottle with some dregs in the bottom, and after a glance the doctor prescribed a small something, passed it to the child, and called the next patient. Other patients came requesting "a note for bronchitis" or some similar malady. With no further formality than "name and address?" this was issued and the patient dismissed. "Notes" and "bottles" were asked for by almost everyone seen, and were supplied on request. Almost everyone seemed to have "a slight touch" of something or other; bronchitis most commonly, occasionally pleurisy, once or twice rheumatism, and once measles.

One patient produced his identity card in lieu of his medical card, to be told "this isn't your medical card." He replied without hesitation: "I know that, and I've been using it here for three months. This is the first time you've noticed."

A number of patients, either because their complaints sounded serious, or because their history was suggestive and they looked really ill, were referred to hospital. This procedure seemed to be known as "sending them through."

Around 4 P.M. the queue, still extending well up the street, was broken off and the front door was locked. I was told that sometimes the housekeeper was posted at the back gate "to stop them coming in there," and that "if we did not do this the queue would remain from 9 A.M. to 9 P.M. and we'd never get our visits done."

The visiting-list was made up, and though I did not count the number of visits to be made it was certainly most formidable. When I asked about records, the reply was: "We have no time for that sort of nonsense. However, we have a secretary who comes in two or three days a week, and makes up records from these old prescription pads. Of course she's months behind." These practitioners do a considerable amount of midwifery and, I was informed, "run our own nursing-home." When asked about antenatal work, the senior member of the firm said: "We don't have much time for that sort of thing." Unfortunately I had no opportunity to pay any domiciliary visits with these doctors, or to see their nursing-home.

The doctors themselves seemed intelligent and made no real effort to explain or excuse their way of practice. Obviously the work had been done in this way for a long time, and the method was accepted, by them and their patients at least, as satisfactory or inevitable. The younger members of the partnership with whom I talked had a high regard for their seniors and claimed that they "don't miss much." One of them, who had been in the practice for only about two years, seemed somewhat perturbed by the nature of things; but "it is all that can be done in the circumstances," he said.

I set these two examples of large industrial practice at the upper and lower limits of "ordinary" industrial practice. Doubtless examples could be found that would be better than the example cited as "good," but I did not see them in England. If better practices existed within the industrial areas studied, I fancy I would have been referred to at least one.

III

Single-handed practices. Small patient-load.

I do not imagine that industrial areas contain many small single-handed practices; but I recall two. Practice A was run by a practitioner who had chosen to work in an industrial area and who limited his list to about 1500 patients, claiming that he could not do justice to more. Practice B was run by a practitioner who had been establishing himself before the war, but on returning from the Services had found his practice almost gone. He had had to begin again to build it up, and when I saw him he had just over 2000 patients. Obviously these two could be called special cases, and so probably could most others which would fall into this group. A few of the doctors would be young and recently started in practice.

Both the men I have mentioned had their surgeries at their homes. In both cases they had adapted two rooms, originally part of the dwelling, to their needs. Both surgeries were reasonably well equipped, that of the elder (practice A) particularly well. His waiting and consulting rooms were comfortably and tastefully furnished, and the latter was well supplied with the essential instruments of practice. This surgery was far more like the type of thing seen in the better-class residential practices than the usual industrial surgery.

The practices covered similar areas, and the housing and economic conditions in the two places were similar, housing being bad in both. There the comparison ceases, and I shall describe them separately. It should be noted that both these practices were locally described to me as "good."

Practice A.—All patients were seen by appointment; a quarter of an hour was assigned to each, but whenever necessary more time was given. Patients on return visits requiring certificates or repeat prescriptions were asked to come at the beginning of the consulting hour, and 10–12 came within the hour. Physical examinations were thorough, and reasonably full records were kept. During my time in this practice I saw no-one referred for an opinion until the case had been investigated as far as could be done in the surgery. When necessary, urine was examined microscopically, and hæmoglobin and blood-sedimentation rates were estimated. If possible, when further laboratory tests were required, a specimen rather than the patient was sent to the hospital.

Minor surgical procedures, such as the opening of superficial abscesses, strapping of sprains, removal of fingernails, and minor sutures, were done in the surgery. Psychological problems received careful attention and a good deal of time was devoted to them when necessary. No midwifery had been done for some years, but the doctor was about to recommence booking cases, because his income had dropped appreciably since July 5, 1948.

Though this had been a dispensing practice for many years, there was no evidence of the "bottle of medicine" mentality. All claims for sickness and other benefits were examined carefully from the social and psychological angle, as well as the organic.

There was ample time for domiciliary visits, and the same thorough routine was followed in them. The doctor was on friendly terms with many of the consultants in the area, and, though he had no visiting rights in any of the hospitals, he managed to see many of his patients who had been admitted, and often did a round with one or other of the local consultants.

Practice B.—With only a small difference in the patient-load of this practice, the doctor was seeing about three times as many people at each consulting hour and making about twice as many domiciliary visits. There was no appointment system.

History-taking and physical examinations were cursory. The doctor told me that he did not attempt to do rectal examinations, but that if a case was sufficiently suggestive of cancer of the rectum he sent it straight to hospital. Wherever indicated, some sort of an examination was made of chest or abdomen, and if symptoms or signs were in the least suggestive of possibly serious organic disease the patient was referred to an outpatient department for another opinion. No great effort was made to define the possibilities before referring the patient.

During my stay in the practice no records were made of any of the patients seen. Files and record cards were kept on what were considered important points, but from what I saw of the cards the notes were mainly on prescriptions issued.

This doctor booked confinements and did most of his own antenatal work. He asked about the patient's health since her last visit, took her blood-pressure, and examined her urine. No records of these were kept unless there seemed to be some abnormality. None of the minor surgical procedures undertaken in the other practice were attempted here: the patient was sent to hospital.

Domiciliary visits amounted to 10–15 a day (except during epidemics, when they were considerably more numerous). This allowed the doctor to spend a reasonable time on each visit; but the actual examinations made were of the same cursory kind as in the surgery.

Rural Practice

I

Three partners. About 10,000 patients. Good cottage-hospital facilities and three small nursing-homes.

This practice, established for almost a century in a town now having 20,000 inhabitants, had never had more than a few hundred on the "panel." There were several other doctors in the town, practising alone or in pairs.

With two senior partners and one junior, the practice served an area extending about ten miles from the surgery, with good road communications. Most of the people were engaged in farming, but the town had some light industry. Both town and countryside could be described as prosperous.

The surgery was a converted shop and residence above the shop. The waiting-room was downstairs and was adequate and well furnished. There was also a dispensary with a dispenser-receptionist working in a small room opening on the waiting-room. Upstairs there were three consulting-rooms, and an office where records were kept and other clerical work was done. A full-time male clerk lived on the premises and worked for all three doctors. The consulting-rooms were spacious and typical of the all-purpose type described previously. They were well equipped both basically and with instruments.

The cottage hospital was run by all the G.P.s in the town, but this partnership made by far the greatest use of it. It was a 50-bed unit, with both medical and surgical wards, a fairly up-to-date operating-theatre, a small department of physiotherapy, an X-ray department, and a small recently acquired department of pathology. This last, though it was not very well equipped, employed a junior and a senior technician and met most of the requirements of the hospital and the local practitioners. Consultant surgeons and physicians visited the hospital once a month, or more frequently if asked.

There were three small private nursing-homes. One was a 5-bed unit for maternity cases only; the other two had about 10 beds each, and an operating-theatre, and took general medical and surgical cases.

To some extent the three partners divided their routine duties. One did most of the surgery, not only for his own practice but for the district; one did some "minor" surgery, such as tonsillectomies an[illegible] [illegible]mies; and the third gave most of the [illegible] duty was worked on a roster system and they relieved one another for days off. All three did their own midwifery, which amounted to 10–30 confinements each per year. The surgeon of the partnership undertook most of the abnormal midwifery for the district, including all cæsarean sections.

There were three consulting hours six days a week, with two doctors working simultaneously at each period. No routine appointment system for consulting hours had been introduced, but special appointments would be made when patients had to come a long way, or where transport communications were bad, or when it was expected that consultation and examination would take a long time. About 15–20 patients were seen by each doctor during a consulting "hour," which sometimes lasted as long as one and a half hours; and as much as twenty minutes would be devoted to a patient needing particular attention. If further or more detailed examination was deemed necessary he was brought back to the surgery by appointment or seen as an outpatient at the cottage hospital. Apart from simple urine-testing, all laboratory tests were done by a technician in the hospital pathology department.

Record-keeping was unsatisfactory, even on the more important and serious cases. Antenatal work was much as described for other practices; notes were made only if some abnormality was suspected.

At the time I was in this practice domiciliary visits were averaging some 10–20 per day per doctor—mostly nearer the lower figure—and I was told that this was usual except during winter epidemics. At this rate ample time could be devoted to those patients who required detailed attention and examination. Though the domiciliary visits involved a lot of driving, roads were good and farms and houses readily accessible, and the time spent "on the road" did not seem disproportionate.

The cottage hospital was used primarily for surgical cases, but a few beds were allotted to medical ones. Difficult surgery was undertaken by the G.P. surgeon, and as little as possible was "given away" to visiting consultants or sent to the larger city hospitals. I was told that potential cases for cæsarean section were kept in the district and admitted to the local hospital as "emergencies" rather than let the case be "lost" to a city hospital. I was also told that the figure for cæsarean sections in this area is 25 times the average figure for the United Kingdom. I have not verified this statement, but in the circumstances the rate would certainly be well above average.

The whole question of the general practitioner with cottage-hospital facilities, and the "excesses" of surgery performed under these conditions, will be considered later in this report.

Compared with those obtaining in industrial areas, the standards of physical examination in this practice were very good. If they were judged against the disciplines and routines of examination in any reasonable hospital, they would seem superficial and not too satisfactory; but they were thorough and comprehensive enough to assure that most organic diseases would not be missed. It was evident that the doctors knew the patients intimately and were constantly watching for aberrations from the personal norm; and within the limits set by time, equipment, and general facilities their routine work would pass as excellent. They paid serious attention to the psychological problems their patients brought them, and though they were obviously not versed in modern psychiatric theory their knowledge of the patients and their understanding of their ways and habits enabled them to give valuable help.

In short, these practitioners were "family doctoring" and at the same time aspiring to relatively good standards in organic medicine. Comparatively, if not in absolute terms, the organisational side of the practice was also good.

II

Three partners. About 10,000 patients. Fair cottage-hospital facilities.

This practice, established for many years in a town now having some 25,000 inhabitants, had also never had more than a few hundred on the "panel." Its general similarity to the one I have just described will at once be noted. Like the other, it was referred to me as a "good" practice, and I am describing it mainly to demonstrate how wide a range of medical conduct is still accepted in professional circles as within this category. The medical people I consulted about my sampling did not classify any rural practice as "bad," though they thought that some of the practitioners were doing too much surgery in the cottage hospitals.

The similarity between this and the previous practice extended beyond the broad description given above: the surgery lay-out, the staffing, and the organisation were all very much the same, except that this practice was less well equipped. But there was a big difference, I thought, in the work of the doctors. Though, like the others, they devoted ten to twenty minutes to each consultation, their standard of physical examination was about the same as I saw in the large industrial practices: it was superficial, restricted to the offending organ, or concerned with some expressed symptom. Similarly, the psychological problems were considered casually and treated by reassurance in a most empirical way. I did not myself see a single laboratory test done in this practice. A bottle of medicine was almost always prescribed, and certification for sickness benefits was generous and unconsidered. The antenatal work I witnessed consisted in a brief chat between the doctor and the expectant mother, without an examination of any kind.

In this particular practice there were many elderly patients, and they were treated with the greatest kindness—but not with medical skill. In the course of domiciliary visits I stood at the bedside of several old people suffering from congestive cardiac failure and receiving, as treatment, continuous bed rest and frequent injections of morphine. One such patient, with a generalised dropsy, had had six months' bed rest and morphine at home without investigation before being admitted to the cottage hospital, where paracentesis abdomini was performed as initial treatment. I also saw several patients who had had a mild "stroke," and they too were bed-ridden and receiving the morphine and reassurance therapy.

Bad as this account sounds, and bad as the practice in fact was, in terms of human kindliness these doctors were doing a job of "family doctoring" which, in contrast with what goes on in the industrial areas, must be considered good. Furthermore, at the more leisurely pace of work, and with some personal knowledge of their patients, I believe they were doing at least an equally good job of organic diagnosis, except for the elderly. Locally, their ability was highly regarded, primarily because they could open an abdomen and remove an acute appendix or untwist a torsion of the ovary; and they were well liked because they were essentially kind and human.

THE VILLAGE DOCTOR

The above type of country-town cottage-hospital practice is almost as distinct from isolated individual rural practice as it is from industrial practice. In many remote areas the country doctor has not moved very far from the horse-and-buggy days; he has learned to use some of the new drugs such as penicillin, and may have caught up on a few new techniques; but essentially he is comparable in most respects to the old family doctor of the last century.

His surgery has often served successive doctors for many decades, and sometimes there has been little change in, or addition to, his equipment over the same period. Occasionally you find the young doctor (or once young doctor) who has started practising in a quiet country village and who has set about revolutionising the way of practice and bringing modern medicine to the villagers; after a time these doctors usually strike a happy compromise between scientific zeal and human relations, and perhaps represent the very best of general practice.

In this realm the doctor is the absolute autocrat, and what he does and how he does it is no more and no less than a reflection of his personal capacity. So a description of this type of practice in any detail would amount to no more than a description of a number of individual men. I shall later say something about the problems which arise from such practices; and I must point out at this stage that many of them (some enjoying excellent reputations) are so badly equipped as to be quite unable to meet a serious emergency, even by way of offering satisfactory first-aid. This in no way alters the fact that the doctors running them are often first-class family doctors. We see again how hard it is to equate the dictates of modern medicine with the essential humanism of our concept of general practice.

Urban-residential Practice

I

One doctor. About 2000 patients. Access to two small nursing-homes.

This practice, about twenty-five years old, had been run by the practitioner for fourteen years, and he had never taken "panel" patients. It was one of the few I visited where the surgery had been built for its purpose, and there were three rooms, though the third had not been used (except for storage) for many years. The waiting-room was commodious, well furnished, and altogether pleasant. The consulting-room was well laid out and well equipped.

The doctor employed no clerical or nursing assistance, but he worked to an appointment system, kept fairly good records, and displayed much better organisational ability than is usual. Appointments were set at quarter-hour intervals, but if half an hour or more was needed to complete a consultation and examination this time was taken. Physical examination was thorough, and during my stay in this practice clinical laboratory tests were undertaken whenever indicated. They were done at the local hospital, but the doctor was having increasing difficulty about this because he had lately lost his place on the hospital staff. Similarly, he had been accustomed to doing his own minor surgery at the hospital, and as his private surgery was not equipped for this purpose he now had to send patients, whom previously he would have had no hesitation in treating himself, to another doctor.

This practice provided an excellent example of the really good doctor who is suffering in every respect from the curtailment of his terms of reference. Through his past association with the hospital, he knew intimately, and was on excellent terms with, his consultant colleagues, and this long association stood him in good stead after his exclusion from the hospital staff. He also knew his patients intimately and was at great pains to handle their psychological problems as well as possible; but at the same time he tolerated no abuse of his services and was certainly not burdened by "silly" claims on his time. He undertook no major surgery at all, but he did a good deal of midwifery and gave thorough attention to expectant mothers throughout pregnancy.

Within the present concept of individual general practice, the work here was as good as one could hope to see. But it was being done under increasing difficulties.

II

One doctor. About 2500 patients. Access to small local hospital and nursing-homes.

This long-established practice, run by the same doctor for the past dozen years, had had about 300–400 patients under National Health Insurance. The consulting-room and waiting-room were adapted from the two front rooms of the residence, and their arrangement gave no guarantee of privacy to either the patients or the doctor's family. Both rooms were tastefully and comfortably furnished, but the chaotic state of the consulting-room made smooth and efficient work very difficult. It was poorly equipped and no pretence was made of keeping records. There was no appointment system, and consultations involved a minimum of physical examination. A considerable amount of dispensing was done, and a bottle of medicine was the usual termination of a consultation.

The doctor had access to the local hospital, but he did not seem to take any great advantage of this and made very little use of the laboratory service, though he sent many patients for radiography. He did no midwifery and apparently had very little to do with the children of the area.

Comparing this practice with the previous one, the bigger demand for service was out of all proportion to the additional 500 patients on the list. The doctor worked really hard in his endeavour to meet this demand —proportionately much harder than the first doctor. But the necessity for this hard work arose from his failure to exercise reasonable discipline with his patients. Though the two practices were both nominated as "good," the first was in fact well above the average of the practices of this type which I studied, while the second was below the average.

Symptoms and Causes

An account of some of the patients who passed through surgeries I visited would make quite dramatic reading. I could list many who gave histories suggestive of malignant disease or other obvious and readily diagnosable conditions, but who left, bearing a bottle of medicine, without having had any physical examination; and I could tell some very sad stories of people dying in unnecessary discomfort for want (in my opinion) of a little elementary medical skill. However, I do not believe that such stories, however striking in themselves, would contribute anything to the analysis or solution of the problems of general practice. When an individual error is pointed out, the usual reply is "we can all make mistakes." This is certainly true in general practice, and the individual mistake pales into insignificance beside the predisposing factors which make serious mistakes not only possible but in some circumstances highly probable. I have concerned myself throughout with these causes and predisposing factors and not with collecting examples of errors. I regard the errors as merely symptoms of the chronic illness of general practice today.

It would be foolish, however, to examine general practice in a vacuum, and before I try to summarise its present state I must say something about the relationship of this branch of medicine with other agencies of medical care.

THE GENERAL PRACTITIONER, THE HOSPITAL, AND THE SPECIALIST

It is difficult to say very much about the general practitioner's relation to hospital and specialist services; for, except in a remote way, he has little to do with either.

He has no direct access to the larger institutions and sees little or nothing of the people who work in them. When he refers a patient he does so either by telephone or with a written introduction outlining the case-history and stating his own opinion. In due course he gets back a written summary of the consultant's views and suggestions, or, if the patient has been admitted for treatment, a statement of the principal things that have been done, with advice about further management.

His other line of communication with the specialist is through domiciliary consultations; but the average practitioner has few of these. Some I have talked with have as few as one or two a year, and I should think that ten or twenty would be quite a high figure.

The degree of liaison between practitioner and specialist varies from place to place. It is least in the industrial areas—i.e., in those practices closest to the large hospitals—and seems to be greatest in upper-middle-class residential areas. Of course, before the introduction of the National Health Service Act, domiciliary consultation was largely a function of the patient's ability to buy the service, and it will be interesting to note what happens now that it can be had by all. Such observations as I was able to make on this point will be discussed when I come to consider the effects of the Act on general practice.

In some places practitioners and specialists move more nearly on the same social plane, which undoubtedly brings them into closer professional contact also. This was particularly noticeable in a relatively small yet highly developed northern city which I visited. There the G.P.S and the specialists are often products of the same school and are not infrequently of about the same vintage. While one may have achieved specialist status and the other has remained a G.P., they have retained mutual respect and friendship, and this is reflected in their professional relations. The same observation applies to Scotland.

In larger cities one would expect to find that at the periphery of the town, where there are large secondary hospitals, the relations between the practitioners in the area and the specialists on the hospital staff would be good; but I have not found this to be the case. Practitioners will often completely by-pass the local hospital (even when it has a good reputation and is well staffed) and send their patients longish distances to see the men they "know." The "knowing" may have been ten or twenty years ago, but loyalties and personal sentiment often seem to outweigh objective judgment. Circumstances such as this certainly do nothing to improve the liaison or relations between G.P. and specialist on a local basis.

Actually the rural G.P. often has more contact with specialists than his city colleagues do; because the specialists periodically visit the country hospitals.

I met one hospital superintendent who used to hold Sunday meetings for the G.P.S who worked in the area round his hospital. He claimed that the attendances and results were good, and knowing the man and his reputation I fully believe they were. A few others say they have tried the same thing, but the attendances and response of the G.P.S were so disappointing that the venture was dropped. Intermittent meetings of medical societies seem to be only as successful as the organising ability and leadership of the local chairman or secretary make them. The many G.P.S with whom I have talked demonstrate a fairly constant lack of interest in this sort of thing.

In brief, I find it hard to imagine any circumstances which would more effectively isolate the general practitioner from the specialists and the hospital services than the circumstances now prevailing in most of the areas I visited.

THE GENERAL PRACTITIONER AND LOCAL-AUTHORITY HEALTH SERVICES

In whatever region or district I worked, I made a point of seeing the medical officer of health, and, whenever possible, of talking with representatives of the various branches of local-authority services—doctors, midwives, nurses, and health visitors. I also saw some examples of their work. However, I was not making a study of local-authority services as such, and my attention was directed to the relationship of the local authority with the general practitioner.

In practical terms it is fair to say that such a relationship hardly exists. Often there is a mutual animosity and distrust. The idea that the local-authority services are complementary to the work of the G.P. is, in my opinion, theoretical; in fact these services are substitutes for some of the work which was once his responsibility but has long since passed from his hands.

The one possible exception to this rule is the home nursing service. The doctors are ready enough to use the nurse to give injections, to do dressings, to give enemas, and to perform other routine nursing tasks; but even so it is rather a one-way business. Except in country districts. I met very few doctors who knew their nurses or had anything to do with them beyond telephoning instructions for them to go to such and such an address and do this or that thing.

Before July 5, 1948, the midwifery and maternity and child-welfare services had in many areas relieved the G.P. of almost all responsibility for conducting confinements or taking an interest in the health and welfare of the normal mother and child. There is practically no two-way communication between the clinic and the practitioner. The clinic doctor or the midwife will inform the G.P. of any abnormalities they discover; but the practitioner seldom seems to give any information to them, or to trouble himself about what goes on at the clinics, even where his own patients are concerned.

More than once I have seen a mother come into the doctor's surgery carrying in her arms a baby three or four months old, and this was the first intimation he had ever had that the lady had so much as been pregnant.

So far as I can ascertain, efforts made to use the G.P. as a part-time worker in the maternity and child-welfare clinics have met with little success.

Some of these issues were highlighted when the Act came into operation. The uneasy equilibrium which had been established between the G.P. and the local authority was disturbed as soon as the question of certain remuneration for maternity services was raised. The doctors, who had yielded a large measure of responsibility to the midwives, now sought to re-establish themselves. They claimed that, as they were licensed to practise midwifery, they were therefore the right people to be responsible for confinements—though very many of them had not done obstetric work for years. The final compromise by which practitioners were reclassified into two classes—those worth £5 5s. and those worth £7 7s. per confinement—speaks for itself.

All the midwives, local-authority doctors, and consultant obstetricians with whom I have spoken expressed the hope that the G.P.S who are now booking midwifery cases will leave the actual work to the midwives and clinics. Many doctors are doing this, but at the same time these incidents have upset the midwives considerably, and, I am told, have had bad effects on midwife recruitment. Certainly they have not improved relations between doctor and local authority.

Many of the same remarks apply to the relationship of the G.P. and the school doctor; but unless financial issues intrude, as they have done in the midwifery services, the present equilibrium is unlikely to be disturbed.

To the average practitioner the health visitor seems to be an enigma. He regards her with something between suspicion and cynicism, and I have not heard of a G.P., on his own initiative, using the services of a health visitor. Admittedly health visitors are more than fully occupied meeting the demands of the tuberculous patients and "new" mothers: but this is not the reason for the doctor's lack of interest in them or for his not seeking their assistance.

I must repeat that the local-authority services, instead of complementing the work of the general practitioner, have in fact assumed almost complete responsibility for some of the work that was once his concern.

THE STATE OF GENERAL PRACTICE: A SUMMARY

1. General practice is a term without specific meaning or definition. There are three distinct patterns, which are determined principally by social environment. These are:

General practice in industrial areas.
General practice in urban-residential areas.
General practice in rural areas.

the fact that the doctors running them are often first-class family doctors. We see again how hard it is to equate the dictates of modern medicine with the essential humanism of our concept of general practice.

Urban-residential Practice

I

One doctor. About 2000 patients. Access to two small nursing-homes.

This practice, about twenty-five years old, had been run by the practitioner for fourteen years, and he had never taken "panel" patients. It was one of the few I visited where the surgery had been built for its purpose, and there were three rooms, though the third had not been used (except for storage) for many years. The waiting-room was commodious, well furnished, and altogether pleasant. The consulting-room was well laid out and well equipped.

The doctor employed no clerical or nursing assistance, but he worked to an appointment system, kept fairly good records, and displayed much better organisational ability than is usual. Appointments were set at quarter-hour intervals, but if half an hour or more was needed to complete a consultation and examination this time was taken. Physical examination was thorough, and during my stay in this practice clinical laboratory tests were undertaken whenever indicated. They were done at the local hospital, but the doctor was having increasing difficulty about this because he had lately lost his place on the hospital staff. Similarly, he had been accustomed to doing his own minor surgery at the hospital, and as his private surgery was not equipped for this purpose he now had to send patients, whom previously he would have had no hesitation in treating himself, to another doctor.

This practice provided an excellent example of the really good doctor who is suffering in every respect from the curtailment of his terms of reference. Through his past association with the hospital, he knew intimately, and was on excellent terms with, his consultant colleagues, and this long association stood him in good stead after his exclusion from the hospital staff. He also knew his patients intimately and was at great pains to handle their psychological problems as well as possible; but at the same time he tolerated no abuse of his services and was certainly not burdened by "silly" claims on his time. He undertook no major surgery at all, but he did a good deal of midwifery and gave thorough attention to expectant mothers throughout pregnancy.

Within the present concept of individual general practice, the work here was as good as one could hope to see. But it was being done under increasing difficulties.

II

One doctor. About 2500 patients. Access to small local hospital and nursing-homes.

This long-established practice, run by the same doctor for the past dozen years, had had about 300–400 patients under National Health Insurance. The consulting-room and waiting-room were adapted from the two front rooms of the residence, and their arrangement gave no guarantee of privacy to either the patients or the doctor's family. Both rooms were tastefully and comfortably furnished, but the chaotic state of the consulting-room made smooth and efficient work very difficult. It was poorly equipped and no pretence was made of keeping records. There was no appointment system, and consultations involved a minimum of physical examination. A considerable amount of dispensing was done, and a bottle of medicine was the usual termination of a consultation.

The doctor had access to the local hospital, but he did not seem to take any great advantage of this and made very little use of the laboratory service, though he sent many patients for radiography. He did no midwifery and apparently had very little to do with the children of the area.

Comparing this practice with the previous one, the bigger demand for service was out of all proportion to the additional 500 patients on the list. The doctor worked really hard in his endeavour to meet this demand —proportionately much harder than the first doctor. But the necessity for this hard work arose from his failure to exercise reasonable discipline with his patients. Though the two practices were both nominated as "good," the first was in fact well above the average of the practices of this type which I studied, while the second was below the average.

Symptoms and Causes

An account of some of the patients who passed through surgeries I visited would make quite dramatic reading. I could list many who gave histories suggestive of malignant disease or other obvious and readily diagnosable conditions, but who left, bearing a bottle of medicine, without having had any physical examination; and I could tell some very sad stories of people dying in unnecessary discomfort for want (in my opinion) of a little elementary medical skill. However, I do not believe that such stories, however striking in themselves, would contribute anything to the analysis or solution of the problems of general practice. When an individual error is pointed out, the usual reply is "we can all make mistakes." This is certainly true in general practice, and the individual mistake pales into insignificance beside the predisposing factors which make serious mistakes not only possible but in some circumstances highly probable. I have concerned myself throughout with these causes and predisposing factors and not with collecting examples of errors. I regard the errors as merely symptoms of the chronic illness of general practice today.

It would be foolish, however, to examine general practice in a vacuum, and before I try to summarise its present state I must say something about the relationship of this branch of medicine with other agencies of medical care.

THE GENERAL PRACTITIONER, THE HOSPITAL, AND THE SPECIALIST

It is difficult to say very much about the general practitioner's relation to hospital and specialist services; for, except in a remote way, he has little to do with either.

He has no direct access to the larger institutions and sees little or nothing of the people who work in them. When he refers a patient he does so either by telephone or with a written introduction outlining the case-history and stating his own opinion. In due course he gets back a written summary of the consultant's views and suggestions, or, if the patient has been admitted for treatment, a statement of the principal things that have been done, with advice about further management.

His other line of communication with the specialist is through domiciliary consultations; but the average practitioner has few of these. Some I have talked with have as few as one or two a year, and I should think that ten or twenty would be quite a high figure.

The degree of liaison between practitioner and specialist varies from place to place. It is least in the industrial areas—i.e., in those practices closest to the large hospitals—and seems to be greatest in upper-middle-class residential areas. Of course, before the introduction of the National Health Service Act, domiciliary consultation was largely a function of the patient's ability to buy the service, and it will be interesting to note what happens now that it can be had by all. Such observations as I was able to make on this point will be discussed

This whole question of "patient abuse" is mostly a matter of speculation. The patient's reason for consulting a doctor is his own anxiety, which nobody else may be able to assess. Nevertheless the intensity of anxiety is largely governed by understanding of its causes, and the person with the most external control over it is the doctor.

Whenever a doctor has had a practice for any length of time, and has exercised a reasonable educational and disciplinary function, he is not a victim of patient abuse; the amount of this he suffers from is almost directly proportional to his laxity in these regards. It is interesting to contrast the current attitude of the doctors in Britain, where "patient demand" is probably now at its peak and where practitioners are beginning to appreciate the advantages of (even partial) emancipation from "patient blackmail," with that of the doctors in New Zealand, who have long since passed through this phase. I shall refer to this again in the appendix on New Zealand.

The demand for service is intimately tied up with the doctor's personal behaviour. I saw many practices where the doctor contended that the demand was very little greater than before July 5, 1948. I saw others, where, though there had been little or no increase in the number of patients covered by the practice, the demand had increased so much that the quality of the work was suffering.

Apropos of this, I met a number of doctors, running practices which before the Act were mainly composed of panel patients, who were actively refusing to keep on the "good paying patients" of former days unless they would come on their N.H.S. list. The doctor's attitude was usually expressed something like this: "I didn't mind wasting my time with these people before the service started, but they're not worth it any more." Various inferences can be drawn from this, but they hardly need elaborating.

I met one practitioner who had had several years' hospital experience before going into general practice, enjoyed a considerable reputation in professional circles, and had many doctors' families on his list. The rest of his practice was 80% industrial and 20% "private," the private part being made up of schoolteachers, clerical workers, skilled artisans, and the like. From July 5, 1948, he kept careful records of the demands for service that patients in the various groups made on him. In the first nine months of the new service the ratio of demand by members of doctors' families, "private" patients, and industrial patients was about 3 : 2 : 1.

Another doctor had built up a large partnership; commencing from humble origins in an industrial centre, he had finished up with a small and select practice of "good paying patients" in a high-class residential area. There were fewer than 2000 on his books and the financial returns were good. Soon after the introduction of the service, this man closed his practice and "retired" to the industrial part of the partnership, taking on a list of about 4000.

I cite these two cases to illustrate the difficulty of estimating, either in absolute or in comparative terms, the increase of work brought by the Act, or the doctor's reactions, private and expressed, to the new circumstances. The size of the doctor's list is *not a good* index of what is actually happening, though of course in the upper ranges (3500 and over), with conditions of practice as they are, there is no disputing that the load is grossly excessive.

The increased load, whatever its weight and nature, has clearly demonstrated points of basic weakness in the present structure of general practice. For these weaknesses the National Health Service Act is not responsible. Blame rests on the service only in so far as it has failed to provide the means of reinforcing general practice, so that it can take the new load.

REMUNERATION

I hesitate to enter the controversy on ways and means of remunerating the doctor. All sorts of extravagant statements have been made about the intrinsic evils of the capitation system of payment. The greatest tangible evil is the fact that it puts a premium on quantity rather than quality of work. It penalises the man with a small practice doing very good work, and it pays handsomely the man with a big list, however bad his work may be. But neither here nor in New Zealand have I seen any acceptable evidence that it operates to the detriment of the doctor-patient relationship.

It is too early to say whether the various devices, such as mileage-rates, special inducement payments, and basic salaries will successfully minimise or close the gap between quantitative and qualitative reward. In any case, we should recognise that the alteration in the method of payment has not altered the structure of general practice.

The desire of the doctor to relate the size of his income, and the manner in which it is received, to "patient benefit" has led to frightful confusion. It has complicated both political and professional issues and has obscured more fundamental considerations.

INTERFERENCE ?

The establishment of executive councils as the bodies responsible for general-practitioner services could be the means of interfering with the manner of general practice or of limiting the doctor's autonomy. I found no evidence that the councils were operating in this way. All those I visited regarded their function as purely administrative.

I always asked the doctors I met or worked with whether there was any sign of interference with their clinical freedom. Only one claimed that there was, and he showed me a circular, sent out by his executive council, which said: "It is considered that all cases of ringworm of the scalp should be referred in the first instance to specialist skin clinics." This was signed by the clerk of the council. Almost certainly the suggestion, or "directive" as the doctor called it, had its genesis at a higher level than the executive council. The doctor objected not to the idea as such but to the way in which it had been put forward, and to the precedent set. He argued that if he could be told what he should do about ringworm of the scalp he could similarly be told about the rest of his work. I agree with him, and I was surprised that many other doctors I saw, who had received the same memorandum, did not draw attention to it. Probably many of them had not read it. However, this was the only instance of direct clinical interference that any doctor gave me.

The chief direct implication of the Act for general practice lies in the provision made for developing health centres. But this is a matter for the future rather than the immediate present, and I shall consider it separately.

INDIRECT IMPLICATIONS OF THE ACT

The changes just considered are responsible for many of the teething troubles of the new service. It may be hoped that time and experience will provide remedies. But while there is little doubt that the present emotional tensions will subside fairly quickly, there is no assurance —indeed *no real hope*—that sound solutions will be found for these problems unless a great deal of thinking and a good deal of fact-finding is undertaken.

For the future of general practice the indirect implications of the Act are much more important than the direct ones, and chief among them is the new emphasis given to hospital and specialist services.

2. The three patterns have evolved from a common parent—the family doctor of last century. Their evolution has been largely a process of adaptation to the growth and development of other medical services, such as those provided by hospitals and specialists. This process has resulted in the decline rather than the progressive evolution of general practice, and in wide departure from both the idea and the ideal of family doctoring.

3. There are no objective standards for general practice and no recognised criteria by which such standards might be established.

4. The reputation of general practice has been maintained through a continued identification with the idea and ideal of family doctoring; but, except in certain circumstances, this reputation will no longer stand up to examination.

5. As a result of the process of adaptation, and the failure to establish and maintain standards, general practice is now worst in close proximity to large hospital and clinical centres and improves in both scope and quality almost in proportion to the distance away from those centres.

6. It follows that the worst elements of general practice are to be found in those places where there is the greatest and most urgent demand for good medical service—i.e., in areas of dense population.

7. The working conditions (surgeries and equipment, organisation and staffing) of many general practices are unsatisfactory. Some are bad enough to require condemnation in the public interest.

8. In some cases—particularly in industrial areas—the working conditions are so bad as to override the abilities and skills of the individual doctor. They tend to reduce the work of both good and bad doctors to a common level.

9. Many doctors have been isolated from hospital facilities and are now working under conditions which make useless much of their elaborate and expensive training, and negate the disciplines taught in hospital and medical school. Some conditions of general practice are bad enough to change a good doctor to a bad doctor within a very short time. These very bad conditions are to be found chiefly in industrial areas.

10. Rural practice represents the last outpost of real family doctoring, and in some respects it has gained more from modern medical knowledge and techniques than urban practice.

11. The over-all state of general practice is bad and still deteriorating. The deterioration will continue until such time as the province and function of the general practitioner is clearly defined, objective standards of practice are established, and steps are taken to see that these standards are attained and maintained.

III. GENERAL PRACTICE AND THE NATIONAL HEALTH SERVICE ACT

DIRECT IMPLICATIONS OF THE ACT

The National Health Service Act has made large and fundamental changes in both hospital and specialist services, and has considerably altered the medical responsibilities of local authorities. It has done little, in any direct or immediate way, to upset the status quo of general practice.

By extending National Health Insurance to cover 100% of the population, instead of the 40% previously covered, it has suddenly thrown a greater load (in terms of volume) on the existing structure of general practice, and by introducing new techniques for remunerating the doctors it has caused a redistribution of income within the profession. But neither of these things implies any basic or direct change in the nature of general practice.

THE GREATER LOAD

It is very difficult to assess the effects of the increased volume of work on any particular practice, or even its scale. It is certainly not possible to generalise about the over-all effects of this increase on the quality of medical care in Britain.

The weight of the patient-load depends, of course, not only on the number of patients registered with a doctor but also on the demands these patients make; and a great deal has been made of the increase in these demands since medical care became free to the patient. On this I have collected a lot of varied opinions, but very little in the way of actual data.

I tried to correlate what was happening in hospital outpatient departments with what was happening in general practice. I thought that hospital figures for periods before and after July 5, 1948, would provide some sort of index of what was going on in general practice. But the figures were not available, and to dig them out of hospital records would have been a long and formidable job. Absolute figures, not broken down into new and return patients and into the various branches of work, are of little value here; but, for what they are worth, those I did see indicated no significant increase in the volume of people attending outpatient departments, and this finding was usually supported by hospital superintendents, consultants, and resident staff.

Opinions collected from the same sources, when they seemed to be considered opinions, suggested that the medical character of the cases coming into outpatients had not materially altered since the beginning of the service. Considerable fuss was made about the time taken up in measuring people for appliances, but this seemed to be a matter of petty annoyance rather than serious grievance.

Opinions as to the increased demands on their time and effort since the beginning of the new service were also collected from all practitioners whom I visited. Almost without exception they said that, while they were seeing considerably more patients in the surgery (they estimated the increase at anything from 10 to 40%), their domiciliary work remained much as before. They generally agreed that in this regard the public were being very considerate, the chief complaint being of late requests to visit. Night work had not increased. Some doctors, indeed, expressed anxiety at the reluctance of patients to call them out in potentially serious cases, and one or two quoted examples of catastrophe narrowly averted.

Almost all spoke of the increased demands for spectacles, for appliances of various types, for drugs and dressings which the patient would previously have bought for himself without consulting the doctor, and for certificates. My own impression, based on all the practices I visited, was that so far as consumption of the doctor's time was concerned it was again a case of petty annoyance. The practitioners who complained most vigorously were usually those who took the line of least resistance and met almost all requests, without protest or discussion, and irrespective of the merits of the case. One doctor used to sign batches of forms certifying the need for ophthalmic tests, and put them on the waiting-room table for patients to help themselves. I saw very few who made any pretence of examining a patient's eyes, and I saw none make a physical or ophthalmoscopic examination before issuing a certificate for eye-testing. Requests for appliances of all types were usually dealt with by immediately issuing a note referring the patient to a hospital department where he could be fitted; I never saw a G.P. "waste" his time by carefully examining before referring.

as represented by housing and possibly nutrition, were relatively good in this area, and there was an excellent geriatric hospital surrounded by rural practitioners, who in my estimation are the best type of G.P.s. But I was unimpressed by the attention given to the old people of the community. Working with doctors within a few miles of the geriatric hospital, I found that they knew little or nothing of its work. The contrast between the handling of a case (say a paraplegic, an arthritic, or a cardiac failure) by the G.P. and by the people in the hospital was most striking.

At first, therefore, one was inclined to say that here, in the specialised hospital, was the answer to many of the problems of old age. But on reflection it was evident that much of the benefit obtainable there could be obtained at home if only the general practitioner would exercise his medical skills on his old patients. The efforts of the hospital to convey this to the practitioners of the area had met with little success.

The important point is that, if geriatric units could be used as an instrument for educating the G.P., and if the emphasis could be put on G.P. home care rather than on specialist-hospital care, the present perspective would appreciably change, and we should need to reconsider our ideas on hospital development for the care of old people. That this could in fact be done is in my opinion beyond question; but the work of the units would need to be oriented in this direction. Failing such action, it is almost inevitable that the success now being achieved in geriatric units will sooner or later receive the recognition it so well deserves and will set an institutional pattern for the care of the "chronic" and aged sick.

THE THREAT TO GENERAL PRACTICE

The socially conscious attitude of the pædiatricians, and latterly the geriatricians, when contrasted with the usual attitude of other branches of curative medicine, has justified their claims to work which normally would not be thought to require specialists. While this socially conscious attitude of mind is to be applauded, the consequences of making new specialties on the basis of whole age-groups of society should be watched very closely.

The current growth of pædiatrics and geriatrics represents another attempt to compensate for deficiencies in general practice in terms of more specialist and hospital care. This trend has been going on for a long time; but if it continues it is bound to result in over-compensation, unnecessary expense, further dehumanising of medical care, and ultimately the elimination of the general practitioner as a responsible person.

The greatest single threat to the future of general practice is the gap between the general practitioner and the specialist. This gap has been widened by the impetus given by the Act to hospital development, and the simultaneous neglect of general practice as an issue of policy.

ADMINISTRATIVE AUTHORITIES AND THEIR RELATION TO GENERAL PRACTICE

THE REGIONAL HOSPITAL BOARD

At this early stage in the history of the new service it is easy to be too critical of deficiencies and weaknesses, many of which are unavoidable and will be ironed out. It is equally easy to be too tolerant and to overlook major faults which might be corrected now but which otherwise will soon be firmly fixed.

The establishment of regional hospital boards, and the granting of the powers vested in them, is probably the most revolutionary feature of the whole Act. The difficulties of staffing these boards and the various committees and subcommittees which work under them, the difficulties of reaching a satisfactory compromise between central and peripheral control, and all the problems which arise from the assumption of new powers by new people strange to them, call for tolerance in comment and patience while early mistakes are overcome.

But the failure to provide a link between the regional hospital boards (responsible for hospital and specialist services) and the executive councils (responsible for general-practitioner services) cannot be classified as an initial or experimental error, and the lack of such a link must be regarded as a primary and serious defect in the structure of the service. The idea that members common to the two kinds of body might form the necessary liaison is not supported by the happenings to date.

The responsibility for this state of affairs rests mainly with the executive councils and others connected with general-practice policy who could take the initiative in defining the rôle of general practice in an integrated medical service. But it is hard to see how the regional hospital people can do their job properly unless they too interest themselves in this fundamental issue. Unfortunately none of the hospital-board members or executives I interviewed showed either a particular interest in, or understanding of, the problems or significance of general practice. They seemed to regard administration of hospital and specialist services as a separate task not concerning, or concerned with, the general practitioner. I do not know of any hospital board which has asked either an executive council or any other body for a statement of policy on general practice; nor do I know of such a statement being drawn up and tendered spontaneously.

Thus hospital and specialist requirements are being worked out with no real regard to the present state, or the future development, of general practice. I saw a good example of this when I visited two hospitals, of similar size and type, which had been included in a previous hospital survey and had lately been assessed for staff and equipment. One of them worked in association with a long-established group practice and the other in association with a number of doctors working independently. The work that was being done by the group completely altered the requirements of the first of these hospitals; yet nobody official had ever visited the group or taken any account of the things that were being done, or could be done, by it. Even in situations like this, where the whole history and development of the hospital had been in the hands of the general practitioner, the future of the hospital now seems to be considered as something apart from him. This is an extension of the attitude which has prevailed in larger hospitals for a long time—i.e., that the general practitioner has no place in hospital work and therefore merits no direct consideration in hospital planning and development.

The senior administrative medical officers hold, at least for the time being, the key position in the activities of the hospital boards. All those I met were either ex-public-health men or ex-members of the staff of the Ministry of Health. From the standpoint of administration this is probably the best background they could have; but from the point of view of medical-care policy, particularly general-practitioner services, it is probably the worst.

Whenever general practice came up for discussion, they drew attention to the surgical crimes of the G.P. working in a cottage hospital. Most of them expressed their determination to eliminate the G.P. surgeon. This seemed to be their focal point for thinking about general practice. Their attitude to the problems presented by industrial practice was one of resignation to the inevitability of that sort of thing, of hopelessness of doing anything about it at its source, and of consequent acceptance of the need to compensate for it through the agency of hospital and specialist services.

I have already given my opinion that:

1. The G.P. surgeon is the chief target in what I term the "attack" on general practice, and there is a tendency to extend the case against him into other provinces of the G.P.'s activity.
2. Up to the present, the development of hospital and specialist services, far from assisting the G.P. to do better work, has depressed both the scope and quality of his work.

I am not suggesting that it is impossible to increase both the amount and scope of hospital and specialist services and simultaneously to upgrade the G.P.; but there is no sign that the new service is going to bring about this desirable end. On the contrary, there is some indication that it is worsening the present unsatisfactory state of affairs.

As at present conducted, the upgrading of the smaller hospital units implies exclusion of general practitioners from the staff; it further implies the employment of many junior specialists, often with no experience of general practice; and it closes the already half-shut door on the G.P.'s chance of entrance into the realm of the specialist. I have just been told of two hospitals upgraded in this way, with exclusion of the G.P. obstetricians of the area. The reason advanced for such exclusion is of course that the G.P. is not the proper person to do midwifery; and similar arguments are brought against the G.P. surgeon, the G.P. E.N.T. man, the G.P. anæsthetist, and in fact any G.P. who shows a particular interest, and attempts to develop a particular skill, in almost any branch of medicine. So long as the general practitioner's province and function is undefined, he is in no position to defend himself against those who would constrict it further.

I met a number of G.P.S, of long experience and real ability, with well-established practices, who had sons either in medical school or recently graduated. These men told me that they had planned to retire relatively early and allow their sons to succeed to the practice; but they had now given up these ideas and were encouraging their boys to seek a different kind of life in one of the specialties. They were moved to this decision not by financial dissatisfaction or fears of bureaucratic controls, but because they foresaw limitation of the scope of the G.P.'s work and responsibility.

CHILDREN

Compared with the other specialties, which concern themselves only with anatomical or physiological parts of the body, the newer specialties of pædiatrics and geriatrics bite more deeply into general practice, because they assume responsibility for whole age-groups of society.

Pædiatrics, the longer and more firmly established of the two, has gained much ground in recent years. As a new and socially conscious group, the pædiatricians have made valuable contributions to both the medical and the social welfare of children, and in a lesser degree to that of mothers. But, unlike most other specialists, the pædiatrician does not confine himself to the more difficult parts of his subject. In fact nothing seems to be too menial for him. Child health, infant feeding, and minor ailments, in which the G.P. has shown a conspicuous lack of interest, have captured the pædiatrician's imagination and have all been drawn into his net. Apart from the obstetrician, he is probably the only practising doctor who can claim to have an active interest in preventive medicine.

No-one would argue that there is no place for pædiatrics, but it is a moot point whether the pædiatrician should take so much of the responsibility for the general medical care of a whole age-group, thus further fractionating the continuity of care and relieving the G.P. of yet another part of his duties. I have observed the work in several pædiatric clinics and have been struck by the large proportion of the specialist's time which is taken up with minor matters which a good G.P. should be fully capable of handling. I would estimate these minor cases at something like 50% of those I saw passing through the clinics. In New Zealand, for example, where midwifery and what one may call the lower strata of pædiatrics form the very basis of general practice, these 50% would never get near a clinic or a specialist pædiatrician, and it is my firm opinion that the mothers and children are better off because of this.

Often I was struck by the anxiety caused to the mother by a clinic visit—I refer here to hospital outpatient clinics, not to local-authority maternity and child-welfare clinics—and also by the failure of the pædiatrician either to appreciate this anxiety or to give time to allaying it. When working in G.P.S' surgeries I was similarly impressed by the obvious anxiety caused by the suggestion of a visit to the hospital pædiatrician, and even more by the anxious state of some of the mothers returning from such visits. Usually this anxiety seemed to be accepted by the doctor as a normal part of the procedure; and again little was done to allay it.

This problem of the creation or fixation of anxiety is not peculiar to pædiatrics. I think I hardly ever sat through a consulting hour without witnessing a case where anxiety had either been created or intensified by a visit to a hospital outpatient department. For this if no other reason, the aim of any good medical service should be the minimum use of hospital outpatient departments compatible with good medical care. Yet the trend seems to be in the opposite direction.

I visited one sick children's hospital where, though the bed capacity had not changed for ten years, the medical staff had increased by 300%, and the vast majority of these doctors were engaged on routine and not research work. I also worked with some of the G.P.S in the environs of this hospital. The best of these could obviously have handled capably many of the problems which they referred almost automatically to the pædiatrician. When asked about specific cases they had referred and the reasons for referral, the answer was always the same: "The pædiatrician is there to be used. Why should we assume the responsibility for the children?"

Thus the mere existence of the pædiatrician impels even the good G.P. to use his services. If the existing demand for pædiatricians is going to be taken as a measure of the real need for them, the figure reached is certainly going to be excessive, and ultimately the general practitioner, in towns, will be relieved of all responsibility for the care of children.

OLD PEOPLE

The position as regards geriatrics is somewhat different, though some of the same considerations apply. The problem of long-term illness in an ageing population has become very important. The G.P.'s attitude and attention to what he calls his "old chronics" is well known and has been mentioned already.

But is it certain that this problem will be best solved by having a new team of specialists, the geriatricians, and much more institutional care? At present, because of the indifference of the G.P. to the illness of old age, it looks superficially as though geriatric units and more geriatricians are the logical, if not the only, solution. Further force is given to this argument when one considers the way in which "chronics" have been dumped on general hospitals and have lingered there indefinitely, occupying beds needed for acute illness and putting up maintenance costs.

I studied the situation in a county where the population is ageing rapidly because the young people have been drifting to the cities. Environmental conditions, as represented by housing and possibly nutrition, were relatively good in this area, and there was an excellent geriatric hospital surrounded by rural practitioners, who in my estimation are the best type of G.P.S. But I was unimpressed by the attention given to the old people of the community. Working with doctors within a few miles of the geriatric hospital, I found that they knew little or nothing of its work. The contrast between the handling of a case (say a paraplegic, an arthritic, or a cardiac failure) by the G.P. and by the people in the hospital was most striking.

At first, therefore, one was inclined to say that here, in the specialised hospital, was the answer to many of the problems of old age. But on reflection it was evident that much of the benefit obtainable there could be obtained at home if only the general practitioner would exercise his medical skills on his old patients. The efforts of the hospital to convey this to the practitioners of the area had met with little success.

The important point is that, if geriatric units could be used as an instrument for educating the G.P., and if the emphasis could be put on G.P. home care rather than on specialist-hospital care, the present perspective would appreciably change, and we should need to reconsider our ideas on hospital development for the care of old people. That this could in fact be done is in my opinion beyond question; but the work of the units would need to be oriented in this direction. Failing such action, it is almost inevitable that the success now being achieved in geriatric units will sooner or later receive the recognition it so well deserves and will set an institutional pattern for the care of the "chronic" and aged sick.

THE THREAT TO GENERAL PRACTICE

The socially conscious attitude of the pædiatricians, and latterly the geriatricians, when contrasted with the usual attitude of other branches of curative medicine, has justified their claims to work which normally would not be thought to require specialists. While this socially conscious attitude of mind is to be applauded, the consequences of making new specialties on the basis of whole age-groups of society should be watched very closely.

The current growth of pædiatrics and geriatrics represents another attempt to compensate for deficiencies in general practice in terms of more specialist and hospital care. This trend has been going on for a long time; but if it continues it is bound to result in over-compensation, unnecessary expense, further dehumanising of medical care, and ultimately the elimination of the general practitioner as a responsible person.

The greatest single threat to the future of general practice is the gap between the general practitioner and the specialist. This gap has been widened by the impetus given by the Act to hospital development, and the simultaneous neglect of general practice as an issue of policy.

ADMINISTRATIVE AUTHORITIES AND THEIR RELATION TO GENERAL PRACTICE

THE REGIONAL HOSPITAL BOARD

At this early stage in the history of the new service it is easy to be too critical of deficiencies and weaknesses, many of which are unavoidable and will be ironed out. It is equally easy to be too tolerant and to overlook major faults which might be corrected now but which otherwise will soon be firmly fixed.

The establishment of regional hospital boards, and the granting of the powers vested in them, is probably the most revolutionary feature of the whole Act. The difficulties of staffing these boards and the various committees and subcommittees which work under them, the difficulties of reaching a satisfactory compromise between central and peripheral control, and all the problems which arise from the assumption of new powers by new people strange to them, call for tolerance in comment and patience while early mistakes are overcome.

But the failure to provide a link between the regional hospital boards (responsible for hospital and specialist services) and the executive councils (responsible for general-practitioner services) cannot be classified as an initial or experimental error, and the lack of such a link must be regarded as a primary and serious defect in the structure of the service. The idea that members common to the two kinds of body might form the necessary liaison is not supported by the happenings to date.

The responsibility for this state of affairs rests mainly with the executive councils and others connected with general-practice policy who could take the initiative in defining the rôle of general practice in an integrated medical service. But it is hard to see how the regional hospital people can do their job properly unless they too interest themselves in this fundamental issue. Unfortunately none of the hospital-board members or executives I interviewed showed either a particular interest in, or understanding of, the problems or significance of general practice. They seemed to regard administration of hospital and specialist services as a separate task not concerning, or concerned with, the general practitioner. I do not know of any hospital board which has asked either an executive council or any other body for a statement of policy on general practice; nor do I know of such a statement being drawn up and tendered spontaneously.

Thus hospital and specialist requirements are being worked out with no real regard to the present state, or the future development, of general practice. I saw a good example of this when I visited two hospitals, of similar size and type, which had been included in a previous hospital survey and had lately been assessed for staff and equipment. One of them worked in association with a long-established group practice and the other in association with a number of doctors working independently. The work that was being done by the group completely altered the requirements of the first of these hospitals; yet nobody official had ever visited the group or taken any account of the things that were being done, or could be done, by it. Even in situations like this, where the whole history and development of the hospital had been in the hands of the general practitioner, the future of the hospital now seems to be considered as something apart from him. This is an extension of the attitude which has prevailed in larger hospitals for a long time—i.e., that the general practitioner has no place in hospital work and therefore merits no direct consideration in hospital planning and development.

The senior administrative medical officers hold, at least for the time being, the key position in the activities of the hospital boards. All those I met were either ex-public-health men or ex-members of the staff of the Ministry of Health. From the standpoint of administration this is probably the best background they could have; but from the point of view of medical-care policy, particularly general-practitioner services, it is probably the worst.

Whenever general practice came up for discussion, they drew attention to the surgical crimes of the G.P. working in a cottage hospital. Most of them expressed their determination to eliminate the G.P. surgeon. This seemed to be their focal point for thinking about general practice. Their attitude to the problems presented by industrial practice was one of resignation to the inevitability of that sort of thing, of hopelessness of doing anything about it at its source, and of consequent acceptance of the need to compensate for it through the agency of hospital and specialist services.

Incidentally, as an outsider, I was struck by the paucity of field work being done by the regional hospital boards. Shortage of staff no doubt limits what is possible, but the result is that many important decisions have to be taken in committee and founded on opinion instead of on investigation. I was also impressed by the tenuousness of coördination between the regional boards and central authority at the Ministry of Health.

For all practical purposes it must be concluded that at the policy level there is no coördination between the regional hospital boards and the people responsible for general-practitioner services.

LOCAL AUTHORITY

The relationship, or rather the lack of relationship, of the individual general practitioner with the local-authority services has already been discussed.

On the introduction of the Act the local health authority, while losing control over municipal hospitals, gained new powers with regard to general practice, in that it was given the responsibility for health-centre development. Except in terms of politics it is hard to see why this responsibility for health centres was vested in local government while responsibility for general-practitioner services was given to executive councils. The failure of all parties interested in the new service to define what they meant by a health centre, and the general acceptance that it had to do with health and therefore preventive medicine, which in turn is identifiable with local-authority services and not with general practice, no doubt made it plausible to hand the responsibility to the local authorities. In Scotland, where a more realistic view was taken and the political complications were less, the Department of Health retained central responsibility for health centres, and the possibilities of fairly rapid and sound development are therefore better than they are in England.

It is natural enough that the local health authorities, having these powers with regard to health centres, should think first of all about their own services and only secondarily about medical care and the general practitioner. It is *not* natural that the G.P., who expressed real concern about health centres at the time of negotiations before July 5, 1948, and who now thinks he has been let down badly over them, and the executive councils, which reputedly look after general-practitioner services, should be taking no active interest in the efforts of local authorities or in the possible alternatives.

The fact that executive councils are confining themselves to administration makes this state of affairs more understandable; but even that does not explain the failure of local authorities to take the initiative and "tie up" with those responsible for general-practitioner services.

The local medical committees similarly show no active interest in the health-centre question. They are interested in a passive way, but they seem to have accepted the edict of "no steel, and houses before health centres" as an absolute reason for doing nothing now.

I could find no evidence that the new responsibilities of local authorities had brought them into any close coöperation or connection with the G.P. Indeed, the construction which is being put on health centres as bigger and better local-authority services, with some secondary consideration for the general practitioner, is widening the breach. The fact that a medical officer of health or a local-authority doctor sits on an executive council, or even on a local medical committee, does not seem to make any difference to the over-all relationship.

Twice I met medical officers of health whose interest was as much in medical care as in problems of public health. Both these men were trying to interest G.P.s individually, and the responsible authorities, in health centres oriented mainly towards the requirements of general practice. They seemed to be having little success; but in both places the general relationship of the G.P.s with the local-authority services was better than I saw elsewhere.

EXECUTIVE COUNCILS

Executive councils sometimes deal in terms of policy with exigencies which crop up from time to time, but never with broad general issues. The local medical committees run a parallel course and seem to be wholly preoccupied with day-to-day affairs. There are any number of these, as can be expected in the early days of a new service, and everyone can plead lack of time to deliberate on underlying principles.

The permanent staff of most of the executive councils have been inherited from the old insurance committees of National Health Insurance, and while they are doubtless very competent to deal with the machinery of the insurance scheme, most of them seem to be well out of their depth when it comes to other matters concerning general practice. This reduces the likelihood of executive councils doing anything more than the most routine kind of job; and yet they are the only official body directly responsible for general-practitioner services.

THE DOCTOR'S ATTITUDE TO CURRENT PROBLEMS OF GENERAL PRACTICE

The British Medical Association has expressed the official attitude of doctors to the National Health Service. Just how far this attitude of organised medicine in Britain represents the summation of individual opinion is open to question. From my contacts with a large number of doctors—some approving the official attitude; some disapproving it; but mostly "ordinary" doctors, asking no more than to be allowed to get on with their job as they see it—I was unable to correlate the thoughtful opinions of the majority with the statements of the organisation which represents them.

It is perhaps significant that these thoughtful opinions rarely find their way into the channels of public communication. This does not imply that any censorship is exercised over them; but they remain unexpressed through the inertia of those who hold them, through a sense of modesty, or through a feeling of the futility of individual effort in issues as vast as this.

So far as general practitioners are concerned, I believe that a feeling of futility and insecurity, more than anything else, has prevented their expressing opinion on policy. Because of this, I am sure we are missing a wealth of experience and wisdom which would be available if general practitioners were given the necessary encouragement and opportunity to put forward their views.

As things stand, general practitioners are having little share in determining their own destiny or professional future, and this is leading to a demoralisation which can only accelerate the decline and fall of general practice.

In the course of this study I sought opinion from men long established in practice and from young men trying to enter it or make their way in it. The same sense of hopelessness pervaded both generations. Some of the best family doctors whom I met were actively discouraging their sons and daughters from succeeding them in general practice: as I have already explained, they believed that the eclipse of general practice is at hand—that it is to be supplanted by more and more institutional and specialist medicine.

It is noteworthy that even these fine family doctors, who for years have acted as family counsellors as well as ministering to the organic needs of their patients, give priority of interest to the organic aspects of their work. The reason for this, I feel sure, is that, within our cultural pattern, the doctor's ability to establish rapport with his patient, and thus place himself in a position to cope with psychological problems, rests largely on his ability to handle physical disease—not only the minor physical disorder but also, to a great extent, the major one. This dates from the time when patients had to rely on the family doctor for almost every kind of medical care; for many people still suppose that he carries this great burden of responsibility—which he rarely does. I have actually met doctors who believe that they must do a certain amount of major surgery or lose the respect or "faith" of their patients; and this is undoubtedly true in some degree.

While the doctors' attitude in this regard could probably be altered fairly rapidly by a reorientation of medical education, the corresponding change in the cultural pattern would probably take generations rather than merely years.

THE CONTRACTING SPHERE

This brings us back to the question of how much responsibility for medical care can be safely centred in one person.

I have drawn attention to the efforts to control the excesses of the general practitioner in surgery, and to the extension of similar empirical control (or limitation) to other parts of his work. Now, looking at the non-organic side of his activities, it is very obvious, in the light of modern psychological and psychiatric knowledge, that it is potentially dangerous to have a "half-trained" doctor handling psychological problems. Yet we are faced with a situation where he does handle them; and moreover one where—the cultural pattern being what it is—the patient accepts the ministrations of the general practitioner as orthodox, whereas he would be suspicious of the "modern heresies" of the psychologist, the psychiatrist, the psychiatric social worker, and the home visitor. So long as this is so, we cannot afford to reject the G.P. by over-curtailment of his responsibility for organic medicine, or to force the new heresies on the public in obedience to the dictates of organic statistics on the one hand and modern psychological theory on the other. The present trend towards institutional and specialist care is in fact a rejection of the general practitioner, an assault on our cultural patterns, and perhaps an indirect admission of inability to resurrect all that is good in general practice and turn it from an anachronism into a contemporary and inestimably valuable service.

Though the behaviour of the doctors I have mentioned was founded on these considerations, they did not express themselves in these words. Some saw the decline of general practice in terms only of a growing contraction of their sphere of activity in the realm of organic medicine: they resented, for example, the threat to their positions on the staff of cottage hospitals. In fact, while the consensus of opinion was that general practice is doomed, they very seldom volunteered a cogent analysis of why this is so, or what ought to be done about it. Nevertheless, once given encouragement and some sort of a lead, these same doctors, from their large personal experience, talked about general practice in a critical and constructive manner which is not often reflected in official or public utterance.

I think it highly significant that good established general practitioners should be advising the younger generation to stay out of this field, so long before their fears may become reality. It is even more significant, in view of what is said by their representatives, that none of the doctors I met expressed serious discouragement in terms of the evils of the capitation system of payment or of the bureaucratic tyrannies which are supposed to characterise the new service.

The foregoing is not an argument for stopping experiment with different kinds of medical care; nor is it a reactionary appeal on my part to retard progress in bringing modern medical knowledge and technique to those who need it. It is, however, an appeal not to throw away what is good in general practice, and relegate this part of medical care to the scrap-heap, but rather to use, reinforce, and bring up to date these good elements. General practice as we know it could, if we wished, be converted into general practice as we like to imagine it; and if this is to be our aim we must not rush too far ahead with the development of our so-called public-health services and specialist services, which are largely attempts to patch up obvious weaknesses in the provision of medical care. It is time that the cause of the weakness, rather than the symptom, received attention.

METHOD OF REMUNERATION

On the highly controversial issue of the capitation system of remuneration I found, as I have said, much less strong feeling than I had been led to expect. Those doctors who had big lists were as well off as previously, or even better off; and no serious complaints were made by this group. I met a few doctors who had previously had a small high-fee-paying clientele and who had been badly hit by the Act—particularly in urban areas where mileage-rates and special inducement payments did not function as a means of subsidy. Rural practitioners, it was argued, would fare worst; yet those with whom I came in contact were relatively unperturbed about either the method of remuneration or the size of the capitation fee. Indeed I found few doctors claiming that the different manner of remuneration had materially altered their way of practice. The few who spoke strongly about patient abuse and disturbance of doctor-patient relations since July, 1948, failed to support their statements to my satisfaction: and in most cases where such statements were made there was evidence of poorly organised and badly disciplined practice which seemed to be of more than twelve months' standing.

The attitude of some of these doctors to the various social and economic groups among their patients was interesting. Especially in the latter months of my study, I noted a growing resentment against those social groups which used to form the paying part of a given practice, with a developing interest in, and attention to, what was once the "panel" part (or its equivalent). This went deeper than a mere objection to the well-to-do patient wanting the benefits of the National Health Service. It arose chiefly from the demands of this social group for more time and attention than their less fortunate neighbours are accustomed to receive, and it was increased by the tendency of better-educated patients to question diagnosis or therapy, to seek reasons for statements and instructions, or even to challenge the doctor's edict.

One subject which cropped up continually in my talks with all manner of general practitioners was that of salaried practice: the hypothetical and real dangers of such a system, and the possibility that it would be the final outcome of the capitation service, were often discussed. I met many doctors who thought that, given reasonable guarantees of autonomy, a salaried service would be preferable to the capitation service. (Of course, emphasis was laid on the need for autonomy.) On this issue, as well as others, I found the thoughtful doctor, both in individual and group discussion, embarrassed when he was identified with the official professional attitude.

ACCEPTANCE OF BAD CONDITIONS

But my attempts to get individual doctors or groups of doctors to appraise the more basic conditions of their work met with little success. The traditional pattern of general practice—i.e., one man doing all his work in a single room with such equipment as he deems necessary

Incidentally, as an outsider, I was struck by the paucity of field work being done by the regional hospital boards. Shortage of staff no doubt limits what is possible, but the result is that many important decisions have to be taken in committee and founded on opinion instead of on investigation. I was also impressed by the tenuousness of coördination between the regional boards and central authority at the Ministry of Health.

For all practical purposes it must be concluded that at the policy level there is no coördination between the regional hospital boards and the people responsible for general-practitioner services.

LOCAL AUTHORITY

The relationship, or rather the lack of relationship, of the individual general practitioner with the local-authority services has already been discussed.

On the introduction of the Act the local health authority, while losing control over municipal hospitals, gained new powers with regard to general practice, in that it was given the responsibility for health-centre development. Except in terms of politics it is hard to see why this responsibility for health centres was vested in local government while responsibility for general-practitioner services was given to executive councils. The failure of all parties interested in the new service to define what they meant by a health centre, and the general acceptance that it had to do with health and therefore preventive medicine, which in turn is identifiable with local-authority services and not with general practice, no doubt made it plausible to hand the responsibility to the local authorities. In Scotland, where a more realistic view was taken and the political complications were less, the Department of Health retained central responsibility for health centres, and the possibilities of fairly rapid and sound development are therefore better than they are in England.

It is natural enough that the local health authorities, having these powers with regard to health centres, should think first of all about their own services and only secondarily about medical care and the general practitioner. It is *not* natural that the G.P., who expressed real concern about health centres at the time of negotiations before July 5, 1948, and who now thinks he has been let down badly over them, and the executive councils, which reputedly look after general-practitioner services, should be taking no active interest in the efforts of local authorities or in the possible alternatives.

The fact that executive councils are confining themselves to administration makes this state of affairs more understandable; but even that does not explain the failure of local authorities to take the initiative and "tie up" with those responsible for general-practitioner services.

The local medical committees similarly show no active interest in the health-centre question. They are interested in a passive way, but they seem to have accepted the edict of "no steel, and houses before health centres" as an absolute reason for doing nothing now.

I could find no evidence that the new responsibilities of local authorities had brought them into any close coöperation or connection with the G.P. Indeed, the construction which is being put on health centres as bigger and better local-authority services, with some secondary consideration for the general practitioner, is widening the breach. The fact that a medical officer of health or a local-authority doctor sits on an executive council, or even on a local medical committee, does not seem to make any difference to the over-all relationship.

Twice I met medical officers of health whose interest was as much in medical care as in problems of public health. Both these men were trying to interest G.P.s individually, and the responsible authorities, in health centres oriented mainly towards the requirements of general practice. They seemed to be having little success; but in both places the general relationship of the G.P.s with the local-authority services was better than I saw elsewhere.

EXECUTIVE COUNCILS

Executive councils sometimes deal in terms of policy with exigencies which crop up from time to time, but never with broad general issues. The local medical committees run a parallel course and seem to be wholly preoccupied with day-to-day affairs. There are any number of these, as can be expected in the early days of a new service, and everyone can plead lack of time to deliberate on underlying principles.

The permanent staff of most of the executive councils have been inherited from the old insurance committees of National Health Insurance, and while they are doubtless very competent to deal with the machinery of the insurance scheme, most of them seem to be well out of their depth when it comes to other matters concerning general practice. This reduces the likelihood of executive councils doing anything more than the most routine kind of job; and yet they are the only official body directly responsible for general-practitioner services.

THE DOCTOR'S ATTITUDE TO CURRENT PROBLEMS OF GENERAL PRACTICE

The British Medical Association has expressed the official attitude of doctors to the National Health Service. Just how far this attitude of organised medicine in Britain represents the summation of individual opinion is open to question. From my contacts with a large number of doctors—some approving the official attitude; some disapproving it; but mostly "ordinary" doctors, asking no more than to be allowed to get on with their job as they see it—I was unable to correlate the thoughtful opinions of the majority with the statements of the organisation which represents them.

It is perhaps significant that these thoughtful opinions rarely find their way into the channels of public communication. This does not imply that any censorship is exercised over them; but they remain unexpressed through the inertia of those who hold them, through a sense of modesty, or through a feeling of the futility of individual effort in issues as vast as this.

So far as general practitioners are concerned, I believe that a feeling of futility and insecurity, more than anything else, has prevented their expressing opinion on policy. Because of this, I am sure we are missing a wealth of experience and wisdom which would be available if general practitioners were given the necessary encouragement and opportunity to put forward their views.

As things stand, general practitioners are having little share in determining their own destiny or professional future, and this is leading to a demoralisation which can only accelerate the decline and fall of general practice.

In the course of this study I sought opinion from men long established in practice and from young men trying to enter it or make their way in it. The same sense of hopelessness pervaded both generations. Some of the best family doctors whom I met were actively discouraging their sons and daughters from succeeding them in general practice: as I have already explained, they believed that the eclipse of general practice is at hand—that it is to be supplanted by more and more institutional and specialist medicine.

It is noteworthy that even these fine family doctors, who for years have acted as family counsellors as well as ministering to the organic needs of their patients, give priority of interest to the organic aspects of their work. The reason for this, I feel sure, is that, within our cultural pattern, the doctor's ability to establish rapport with his patient, and thus place himself in a position to his behalf. His views have been severely limited by the political and emotional considerations which have governed professional policy since the Act was first mooted, and in another way even more severely limited by the deeply rooted traditions of the British "family doctor." But I found that whenever these considerations could be temporarily laid aside, and he could be induced to think critically, he had a valuable contribution to make to the whole field of thought on medical care.

The attitude of the young doctor to general practice is of special importance for the future. Medical education at present tends to direct the student away from general practice, and it is certainly not designed to equip him fully for this type of work. Before the introduction of the Act, economic and social pressures obliged a large proportion of medical students to accept general practice as the easiest way to a reasonable livelihood within a reasonable period of time. Nobody would suggest that this was a good means of recruiting general practitioners, but at least it was a means. Today, however, the National Health Service Act has lessened the economic pressure which previously kept some people out of the specialties, and has added few if any inducements for the young doctor to go into general practice. Over and above this, it has put new obstacles in his way.

Even in the hypothetical under-doctored areas, of which the Medical Practices Committee has published long lists, vacancies by death and retirement are few; and sometimes the circumstances in which they have been filled have been such as to discourage candidates from trying again. At the moment the one easy way into general practice is to secure an assistantship in a busy urban practice with the possibility of later partnership. But in the circumstances prevailing in this type of practice it is a shame to see potentially good doctors entering through this channel, since their chances of improving the bad conditions to which they are going are very slim, while the chances of their own retrogression are very great.

The attraction of an apprentice appointment with an approved established practitioner is not really very strong, and so far few such appointments have been made.

The very few young doctors I met who had entered general practice at or about the time the Act came into force were in difficult circumstances and looking for a way out. In section II I described the case of a very able young practitioner who, because he tried to exercise a wide range of medical skills, was regarded as a professional oddity, and who was facing financial disaster because of the limited nature (volumetrically) of his practice. He is perhaps an extreme example, but still an example, of the difficulties and the discouragement which confront anyone with a genuine interest in this type of work. Another illustration is provided by a doctor in a large city where one would imagine that establishment in practice was much easier. He had a senior qualification (M.R.C.P.) and a very strong desire to make his career in general practice. At the time I saw him and witnessed his quite superior work he had been in practice for about eighteen months. He then had some 800 patients on his list, a considerable overdraft at the bank, and a family to support. He had set his own deadline at 1500 patients on his panel by early 1950, failing which he would retreat from general practice into some form of specialist work which offered an assured future and less financial worry.

To the young doctor, as to the old, the promise of health centres as at present conceived is almost meaningless, though to the young perhaps it is not quite the same bogy. The new ideal certainly does not permeate back into the years of undergraduate training, and it is unlikely to have any appreciable effect on recruitment to general practice in the foreseeable future. And it is these foreseeable years ahead which are going to determine the patterns, quality, and nature of medical care for a long time to come.

I cannot report that I found any more spontaneous constructive criticism of general practice among young doctors than among old. Unless they are given a lead, it is useless to look to the latest generation to advance the field of general practice in any radical or fruitful way. They are as closely bound by tradition and the status quo as the generations preceding them; and, though they may resent the present nature of general practice, they tend either to accept it philosophically or to escape into other branches of medicine.

Nevertheless, I found many significant inconsistencies between the opinions of a large number of individual doctors and their opinion as represented by the spokesmen of the profession. More important, I found that, given encouragement, these same doctors, who apparently had nothing more to say than has been said officially, were ready to make a contribution to the planning of both their own future and the future of the medical service as a whole. It is to be hoped that they will be given the opportunity.

HEALTH CENTRES

Both before and after the introduction of the National Health Service, the promise of health centres represented the chief hope of the general practitioners for a "new deal." But though there was much talk about health centres for the future, this future has since been defined as the time when we have more steel, more building materials, more labour, and more money. Many practitioners now regard the promise of health centres as a political trick, designed to gain their support at the time of the negotiations, or at least as an unfulfilled promise whose fulfilment is now unlikely. There are still the optimists who see the health centre as the panacea for all the disorders of general practice; but few of this group can explain what they mean by a health centre, much less show the way to translate it into reality.

Apart from recent deliberative work by the Health Centre Committee of the Central Health Services Council, the only positive steps towards development of health centres have been taken by local authorities. This is natural in so far as responsibility for health centres has been vested in local government; but it has led to an interpretation of the health centre primarily as a large building in which to house the personal preventive health services—maternity and child welfare, health visiting, school medicine, &c.—with only secondary and small consideration for the work of the general practitioner.

Whatever the value of such a health centre may be, it will do little or nothing to improve the standards of general practice. Moreover, general practitioners may refuse to work in a centre of this kind. The vast majority of them are prejudiced against, and suspicious of, local-authority services, even at their present level of development, and for this if no other reason few doctors already established in practice will want to submerge their independence and individuality, as they see it, in the larger machinery of new local-authority health centres. Also there are more material objections—notably the benefits of tax allowances while they remain in their own surgeries.

Many local authorities have been very active in planning health centres, and have committed large and expensive schemes to paper. Perhaps fortunately, however, the great majority have been deterred by shortage of money and materials from proceeding at once with their projects. While they are held up there is time to think again about health centres and to define and design some functional units which might set the course for a better comprehensive medical service.

or can afford—is firmly established and readily accepted as being, if not "the best of all possible worlds," at least the best attainable for the time being. The doctor who worked in an unattractive surgery almost always criticised it from the point of view of his own and his patient's comfort, but very seldom from a functional point of view. The doctor with a nicely appointed surgery, though this was functionally little or no better than the other, usually had no criticism to offer, and often took pride in an establishment which, as regards ease and efficiency of work, was indeed very bad.

This limited outlook on general practice, by the general practitioner himself, is quite as important a factor in retarding health-centre development as is his expressed disinclination to sink his individuality or independence in the cooperative effort of a group. The one bright spot in this otherwise gloomy sky is the fact that, once shown possibilities beyond the present narrow and ever-narrowing limits of general practice, he exhibits a latent enthusiasm, and often a breadth of vision, not to be suspected from his normal conduct and attitudes.

The lack of critical faculty among doctors is curious. A well-trained man will throw over the hard-won disciplines of clinical training, and accept the stultifying limitations of general practice within its present concepts: a really good doctor will divide his working time between a well-equipped, well-run cottage hospital, and a poorly equipped, badly run surgery, without apparently noticing his changing environments of work. Such acceptance of bad conditions has a deadening effect.

REFRESHER COURSES

Efforts have long been made to help the general practitioner to keep abreast of modern knowledge and technique, and to encourage him to maintain standards of work. The so-called refresher courses have been the means mainly used for doing this, and there is much discussion about providing more of them and about ways of freeing the doctor from duty so that he may attend them. But many of the more thoughtful practitioners are sceptical about their value. My own opinion is that, with conditions of practice as they are, these refresher courses do the general practitioner about as much good as an injection of adrenaline does a patient with terminal heart-failure.

AID FROM SPECIALISTS

The attitude of the general practitioner to the specialist naturally varies from doctor to doctor and from circumstance to circumstance; but several points about it need to be noted. At the higher levels of work, exemplified by advanced surgery or medicine as practised in large hospitals, the respect of the G.P. for the good specialist is absolute and unqualified. But at the lower levels of work, as represented by domiciliary and some aspects of outpatient consultations, he does not show the same confidence. And it is at the domiciliary level that practitioner and specialist have most contact.

The line of demarcation between the patient who can be treated at home and the patient who requires hospital care is fairly clear so far as acute diseases are concerned. Hence the general practitioner rarely wants what one may call an emergency domiciliary consultation—his view being that anything as serious as this is not a matter to be debated in the bedroom. It is chiefly in the case of long-term or chronic illness, where there is no clear line of demarcation, that he needs the specialist's help in the homes of his patients. But as, on the whole, both G.P. and specialist lack interest in the chronic medical diseases, particularly those of old age, the demand for domiciliary consultation is not very great.

Thus the good general practitioners whom I met made little use of, and felt little need for, specialist assistance in the home. Many of them said that they have no more than three or four such consultations in a working year, and sometimes not that; and in retrospect they doubted the need for even these few. The specialists whom they called in could not help them much, they thought, with illness in old age. Indeed, so far as these good general practitioners are concerned, the chief reason for calling a consultant is to relieve the anxiety of relatives or the patient; they seldom expect any help for him physically. Such practitioners have made little or no more use of domiciliary consultation since the Act made it generally available.

One good practitioner with whom I worked used the domiciliary consultation for purposes of personal tuition: he collected a number of interesting cases and then arranged for one or more specialists to see them and discuss them with him on some suitable afternoon. While such an arrangement carries obvious benefit to both G.P. and specialist (and probably to the patient), it is perhaps an unnecessarily expensive mode of instruction, and something of an abuse of the system.

In the whole course of my study I did not attend any domiciliary consultations, and I had difficulty in ascertaining how this service is being used. Some practitioners spoke of checking their therapy in chronic or long-term cases (particularly cardiac); but they added that in fact they got very little useful assistance from the specialists. A few expressed satisfaction at being able to call in a specialist in cases involving children—particularly an otologist in cases of otitis media and possible mastoid. But I think the object of the consultation, as they saw it, was to relieve the parents' anxiety as much as to confirm their own opinion.

The relief of genuine anxiety in the patient or his relatives is certainly a very good reason for a domiciliary consultation; but I doubt whether this was the purpose for which the service was provided. The point that impressed me most was that the really good G.P. had, or believed he had, little need to call the specialist to the home, and little (or infrequent) desire to do so. On the other hand, the G.P. of lesser quality could legitimately call in specialists much more often than they were really needed.

On three occasions I met general practitioners who, in all good faith, were calling in young consultants in order to help them financially and get them established. This kindly personal gesture was, of course, billed back to the taxpayer. There was never any question of dichotomy.

From my observations and questions I can only conclude that the good doctor felt little need for specialist assistance in his everyday work as at present constituted, and had little faith in the specialist's ability to do more than he could himself. The less good general practitioner, if self-assured, took the same line as his more competent colleagues; if not self-assured, he used the specialist to compensate for his own weakness.

With general practice as it is today, there is little likelihood of domiciliary consultation being applied properly: indeed until the province and function of general practice has been determined, and real standards have been established, it is useless to speculate on the proper relations between the specialist and the general practitioner in domiciliary work. Both in money and in time, domiciliary consultation is a very expensive means of compensating for weaknesses in general practice; and in present circumstances it is a very dubious means of trying to correct these weaknesses at their source. Perhaps the greatest benefit is to the specialist, who is brought out of his world of institutional medicine and into the world of his patient.

THE PRESENT AND THE FUTURE

In general, I found the attitude of the established practitioner to the new health service only a pale reflection of the vehement stand taken by organised medicine on

The relationship of local-authority services with such a centre must be considered very carefully. Where such services are functioning even reasonably well, even under makeshift conditions, no elaborate provision should be made for them, in the first instance, within the health centre. Offices should be provided in the health centre for representatives of various branches of local-authority services (e.g., home nursing, midwifery, and health visiting), and the work of these people should be coördinated with that of the doctor working in the centre, who should in turn be encouraged to use these services to the full. Once equilibrium and understanding have been established between the G.P.s and the local-authority personnel—by no means a forlorn hope, given these conditions—the question of shifting the local-authority clinic into the health centre can be considered realistically instead of theoretically.

INDIVIDUAL AND GROUP

The ideal of "family doctoring" is still an excellent, desirable, and probably attainable ideal. However, the horse-and-buggy days are far behind, and it is absurd to try to recapture the 19th-century concept of the benign old doctor in his frock coat and silk hat sitting through the night, awaiting the pneumonia crisis or the delayed arrival of the first-born. Our task is rather to resynthesise all that is good in this concept and discard all that is anachronistic.

In this modern age such a resynthesis implies team-work between doctors, nurses, social workers, and technicians, with the general practitioner as the coördinating agent of the team. My own belief is that, as obstacles to such team-work, the so-called rugged individualism of the average doctor, and his antipathy to any form of organisation or imposed discipline, are much overrated. The general practitioner has acquired a position of great personal power, and naturally he is not prepared to yield any of it without adequate compensation. By this I do not mean merely financial compensation. The kind of compensation I chiefly have in mind is the opportunity to do better, more useful, and more satisfying work.

Our task, as I see it, is to re-establish general practice and make it the basis of a positive preventive programme. And I suggest that, as a first step, we should form "basic group-practice units" which could be developed quickly and become the nucleus of future health centres.

THE BASIC GROUP-PRACTICE UNIT

The primary consideration is personnel, not buildings. In the first instance any shell which could be renovated and adapted might serve to house the unit.

The number of doctors who would work together would be determined by population density and the nature of communications to the site. I picture small units of 6–10 doctors, looking after 15,000–25,000 people. The unit would be fully staffed with nurses, clerical assistants, and some form of all-purpose technician who could undertake urinalysis, blood hæmoglobins, sedimentation-rates, and the like. It would be furnished with all the equipment necessary for a good G.P. service.

The crucial question is, how can the incumbents of existing general practices be enticed to coöperate in these circumstances? And now that responsibility for health centres has been vested in local authorities, how can such a programme be made to work?

If conditions for doing good work are offered, and if assurances of professional autonomy can be given, I believe that the problem of recruitment will largely solve itself. The individual doctor, apart from running his car, should have no overhead expenses to bear; he should certainly not be charged even the non-economic rent which is at present mooted. (I found the idea of even a small rental charge a positive deterrent to coöperation in any such project—quite apart from the negative deterrent of loss in tax-rebates for the doctor who gives up all his private practice.) Under such an arrangement very good terms of service should be possible. For example, it would be practicable to offer good and regular vacation and study periods. (The present offer of refresher courses, even with the provision of paid locums, is merely pie in the sky so far as many general practitioners are concerned.) These inducements, once made realities, would strongly attract both present and future practitioners to the "basic group-practice unit."

I have suggested units of 6–10 doctors looking after 15,000–25,000 people. This sets an average of 2500 patients, instead of the permissible 4000, on any one doctor's list. But with the removal of all overhead expenses, and with the other inducements offered, the financial return from this number should be enough to attract anyone except perhaps those whose lists are at present full; and we should further be able, under these conditions, to recruit young doctors in large enough numbers to maintain a ratio of one doctor to 2500 patients.

Group practice is sometimes commended on the ground that it enables the good G.P. to do specialised work and thus make his way into a specialty. But if the conditions of general practice are made sufficiently satisfying, the desire to be a specialist may lessen, and general practice may then compete for the very best medical graduates.

At the "basic group-practice unit" level of development it will certainly be possible to integrate the general-practitioner services with the hospital and specialist services, and there will be no difficulty in bringing the specialist into the unit. (At present this cannot be done.) But, for emotional and political reasons if for no others, it will be necessary to go warily with the introduction of local-authority services, and at the outset no local-authority clinics should be brought into the unit, though, as I have said, an initial liaison should be formed by providing offices for representatives of the local-authority agencies most closely allied to general practice—e.g., home nursing, health visiting, and midwifery. From this liaison the more comprehensive type of health centre should eventually develop.

The capital expense of setting up such units should not be great; but in the circumstances it is hardly a burden to be carried by local authority. The most satisfactory solution would seem to be grants-in-aid from central funds to the local authority, to be spent within the terms set down.

ADVANTAGES

Only on some such basis as this is there a chance of correcting the paradox that general medical care is at its worst in closest proximity to the large clinical centres—at its worst not only for organic reasons but equally for human and psychological reasons. Again on this basis it should be possible to remove much of the empiricism, in diagnosis and therapy, at present prevalent in general practice, and to begin the development of some effective clinical and human research, which in itself would do much to raise the status of such practice.

There is also the question of the doctor as a teacher. He is potentially perhaps the most important of all teachers: he can and often does influence individual and family conduct to a much greater extent than all the other agencies of health education put together. Yet the approach of the average doctor to this part of his responsibility is even more empirical than is his approach to organic medicine. The same factors in a basic group-

WHAT KIND OF MEDICAL CARE ?

The health centre is merely a mechanism, a means to an end and not an end in itself; and unless we can define the end we may as well forget about the means.

If I am correct in setting down the three determining factors of the quality of general medical care as

1. The general social environment
2. The doctor as an individual
3. The immediate environment in which the doctor works

and in claiming that (3) is the only immediate variable and one which can greatly influence (2), then health centres can become the chief factor in raising the quality of general medical care.

As these three factors are by no means constant, there can be no absolute definition of a health centre: the needs of different environments will have to be met in very different ways. Nevertheless it should be possible to establish some criteria for what one might call a theoretical optimum health centre, and then to adapt this to different places and conditions. If we are to do this, we must clear our minds of two ideas:

1. That general practice, as it exists at present, is good or even good enough to meet the needs of any community.
2. That health centres are concerned primarily with preventive medicine as we recognise it at present.

We must then reverse our thinking on hospital and specialist services (medical and ancillary): instead of considering how far we can build these up, we must consider how far we can dispense with them. For both human and economic reasons, we should work from two premises:

1. That as many people as possible should be kept *out* of hospitals—whether as inpatients or as outpatients.
2. That the medical care of the patient should be integrated, not fractionated.

On this basis the optimum health centre must be, first and foremost, a high-grade diagnostic and therapeutic centre; which implies good (if necessary elaborate) equipment and all the people necessary to use it. Continuity of responsibility for medical care of a patient cannot be achieved unless the general practitioner assumes high-level responsibility in a wide range of activities. It is true that there is virtually nothing in his work which some specialist cannot in theory do better; but we must firmly resist the conclusion that therefore we must keep on fractionating and specialising.

Admittedly, general practitioners working with limited equipment and in isolation can easily become dangerous through taking on too much responsibility, but in a health centre well-staffed and well equipped it should be possible to minimise such dangers and ascertain by experiment the level of responsibility which suits practitioner and patient best.

APPLYING THE PRINCIPLES

There are very few places in England where the establishment of an "optimum" health centre is possible: except perhaps in rapidly expanding towns, medical services cannot be planned entirely afresh. So we must think mainly in terms of adaptations of the "optimum" which will fit in with the services already provided by the general practitioner, the hospital, and the local authority.

Our object will be to change the working environment of the G.P. and make it possible for him to do better work and to retain, instead of discarding, the good disciplines of medical school and hospital. If this one thing can be done, a lot of other difficulties should be overcome with relative ease. The schism between hospital-specialist and G.P. services will narrow rapidly instead of widening as at present, and the relationship—or rather the balance of power—between local-authority services and general practice should improve.

Though, in my opinion, it is impossible to draw up a blueprint for a widely applicable prototype health centre, we can set down some indispensable requisites—namely

1. Separate and private units for consultation and examination by each doctor working in the centre.
2. Adequate personal equipment for each doctor.
3. Such nursing staff as is needed to relieve the doctor of unnecessary and time-consuming duties.
4. Such clerical staff and office equipment as are needed for proper organisation, running, and record-keeping.

To these, various additions (differing in different circumstances) will be necessary. For example

1. Laboratory facilities and technicians.
2. Radiological facilities and technicians.
3. Physiotherapeutic facilities and physiotherapists.
4. Rooms for visiting specialists or consultants.

To this medical-care nucleus can be added offices for local-authority services and personnel, and for such welfare functions as may be considered desirable in given circumstances.

In the present situation, both medical and economic, priorities of attention must be allotted. Number 1 priority should go to general practice and not (as now) to local-authority services, and it should go to the worst part of general practice—i.e., general practice in dense urban areas.

In these industrial areas, where the level of general practice is low and where hospital and local-authority services are highly developed, it is unrealistic to think in terms of elaborate health centres. It is equally unrealistic to set out to duplicate an already existing service: for example, in a health centre adjacent to a large hospital unit it would be silly to have expensive diagnostic equipment. Nevertheless the health centre will fail in its purpose unless the necessary facilities are made available to the people working in it.—And I do not mean available in the sense they are available already, when a G.P. can send his patient to a hospital outpatient department and in course of time get back a brief report on what ought to be done (or what has been done) for the patient. The G.P. must have open access to these diagnostic facilities and to the specialists and consultants who are nowadays working in isolation from him.

The health centre should very largely replace the outpatient department. This does not merely imply changing the venue of the department; if it did, no useful purpose would be served. It implies cutting out the episodic care which characterises present outpatient work, by bringing the specialist into the health centre, where he should do the equivalent of his outpatient consultations in the presence of the G.P. concerned with the particular case. The G.P. would then be responsible for coördinating the efforts of the various specialists who handle the patients and for the continuity of care. More than anything else, this is a problem of organisation—and not a particularly difficult one. If the work and responsibility of the G.P. is upgraded and his facilities are improved, the volume of outpatient department work (or its equivalent in the health centre) will be considerably reduced (vide Appendix II).

In large urban health centres a good case can now be made out for the full-time employment of a consultant physician, who would be continuously accessible to all the G.P.s working the centre and who could follow up all cases which interested him. If a consultant physician, to remain at consultant level, must have hospital beds and inpatients, that could be arranged; but the bulk of his time should be devoted to work within the health centre and domiciliary work associated with this.

In the "optimum" health centre similar arguments can be adduced for full-time radiologists, pathologists, &c., working in the centre; but, as I have said, there will be little call for the "optimum" type.

(e.g., industrial practice). This is the result of the widening schism between the specialist and the general practitioner, and inability to see beyond the practitioner's few but dramatic sins of commission (e.g., surgical) to his many more serious, if less obvious, sins of omission (e.g., missed or mistaken diagnosis).

15. With increased inducements for the young doctor to enter the specialties, and a decreasing scope for work in general practice, the latter is becoming an unattractive proposition. Furthermore, it is difficult for the young doctor with a genuine interest in this field to find a satisfactory way into it. The easiest way is through busy urban practice, and under prevailing conditions this is the least satisfactory way.

16. Unless these conditions are changed, potentially good doctors will be devalued without elevating the quality of practice. Similarly, any hope that financial reward alone will attract good senior practitioners back to these bad conditions is illusory: the good doctor will only be attracted into industrial practice by providing conditions which will enable him to do good work.

17. This question of terms and conditions of practice is of primary importance. The defects of general practice cannot fairly be attributed to the defects of medical education. However inadequate may be the teaching of social and psychological medicine, the teaching of clinical disciplines is good; and bad conditions of practice can, do, and will continue to negate the most conscientious teaching efforts in the newer and more abstruse field of social and psychological medicine.

18. Against this background the few inducements—such as refresher courses with paid locums, and traineeships—are of very little value either as attractions or as a means of raising standards.

19. The present conditions of general practice, and the gloomy outlook for the future, have produced demoralisation in many thoughtful members of the profession. The ideas, ideals, and real dissatisfactions of a considerable number of doctors are not reflected fairly or fully by organised medicine, which has fought so vigorously for what have been called terms of service. With opportunity and encouragement, general practitioners could make a valuable contribution towards planning as well as operating the medical services.

20. If the present trend towards more and more hospital and specialist care continues, it must result in

(a) The elimination of general practice as an effective agency of medical care.

(b) The substitution of hospital, specialist, public-health, industrial-health, and similar less personal services.

(c) The breaking of the one remaining link which gives the patient some continuity of care, and the removal of a focal point for dealing with the non-organic problems—the psychological, economic, and social worries of the people.

Quite apart from human values, it is doubtful whether the policy of concentrating on hospital and specialist care is economically justifiable or even possible, and its hazards will certainly not be lessened by drifting into it.

Recommendations

In spite of this grim analysis of the present position and future prospects, the opportunity to re-establish general practice is still open.

First, an attempt should be made to define the future province and function of general practice within the framework of the National Health Service. This deliberative task should, in the first instance, be undertaken by the people most concerned—namely, "ordinary" general practitioners.

Secondly, basic group-practice units, such as I have described, should be formed as soon as possible. There is real urgency about launching this experimental work; for relatively soon the new patterns of hospital and specialist care will be firmly established and everything will be fitted into them. If that happens it will then be virtually impossible to do very much about general practice.

APPENDICES

I. GENERAL PRACTICE IN SCOTLAND

In the absence of recognised criteria it is very difficult to draw comparisons between practice in one place and practice in another. But after examining practice in Scotland, by methods similar to those I used in England, I came away with the firm impression that, all in all, its quality is higher than that of the English equivalent. I do not claim that the best English practice is not at least as good as the best Scotland can show; but if one can admit an average for the diverse types which go to make up what we call general practice, then in my opinion Scotland is in front.

A DIFFERENT ATTITUDE?

The attitude of most general practitioners to both local and central authority, as represented by city and county health departments and the Department of Health for Scotland, seemed more reasonable and cooperative than that of English doctors to the corresponding authorities here. Though it could not be said that the relationships were by any means ideal, for the most part they were at least workable.

In England any association, real or imaginary, between my survey work and local or central authority militated against good relations and created obvious suspicion. In Scotland, on the other hand, wherever I went I found I could use either a local authority or the Department of Health as a means of introduction to general practice, without embarrassment and without arousing any serious misgivings. Indeed in one part of Scotland I actually travelled with an officer of the Department, who accompanied me into the various practices I visited; and the doctors were quite as frank in his presence as if I had been alone. In England, on the few occasions when I was introduced by such an officer, I found relations with the doctors strained until I had explained my association with, and established my independence of, officialdom.

The explanation that has been offered me for this difference—that it is merely a matter of the size of the community—is not good enough. The relationships even in country towns in England are often worse than comparable relationships in big cities in Scotland. There is a basic difference in attitude of mind.

This difference in attitude is reflected in other ways. In England discussion with general practitioners on the new health service usually centred on the size of capitation fees, the number of patients on the list, mileage-rates, basic salaries, and so on, until it was steered into professional as distinct from commercial channels. In Scotland I found much more spontaneous interest in professional issues such as the quality of medical service, the relation of general practice to hospital and specialist services, and the development of health centres.

I do not want to give the impression that I am attributing all good to the Scottish doctor and all bad to the English. This is not the case at all. But there is an appreciable difference.

practice unit which would allow the G.P. wide diagnostic and therapeutic responsibility, while simultaneously creating safeguards against excesses, would tend to operate also in relation to his educational function.

That the group-practice health centre would improve medical care is almost self-evident. To bring together a number of people working on different aspects of a common problem, to provide them with facilities and conditions better than those they have had previously, and to offer them professional incentives to improvement—all this seems bound to result in a better deal for doctor and patient alike. But there are many sceptics, and the only way to satisfy them is by practical demonstration—I mean really practical demonstration in which the sceptics themselves have the opportunity to participate.

AN EXISTING GROUP

In section II I described the only real group practice I visited in England.

The doctors had designed and built their own clinic, which was extremely well equipped, and they employed nursing and semi-trained technical staff as well as clerical assistants. They claimed that their overhead was in no way incompatible with their income from an average of 2500 patients per head. The range of work of the four practitioners and their trainee assistant was comparable to that described for good G.P.s in New Zealand, and though they undertook obstetrics and a large amount of surgery (against which a strong case could be made) they were by no means overburdened. The record-keeping was comparatively good, and the standards and thoroughness of physical examination as high as any I saw in Britain. The head of the group told me that they had not suffered from "patient abuse" since the introduction of the new service, and it was obvious that their ways of practice had not been altered by the terms of the Act.

Judged on premises, equipment, and record-keeping, which can be assessed objectively, this practice was in advance of anything else I saw; and my subjective impression of the standards of work led me to think of it as a beacon in the darkness. Yet in its eighteen years of existence it has received no official or professional attention, and, as I have mentioned, the survey committee which looked at the cottage hospital where these doctors work did not so much as call at the "group clinic" to see what went on there. Fearing that they will in the long run be eliminated from this hospital, at least one of the group contemplates turning to a specialty.

THE FIRST STEP

Though I heard of other such groups existing in various parts of the country, I did not have the opportunity to visit any. But I have no doubt that even the most simply organised group offers an overwhelmingly better medical service than that of individual practitioners.

Even the most elementary steps towards organising the present chaos of individual general practice must result in improved medical service and a fairer deal for doctor and patient, and I am sure that these elementary steps should be taken before any grandiose or idealistic experiments in health-centre development are attempted.

The future of general practice depends on our ability to give definition to a concept which is at present nebulous. Having designed our ends, we must design means to achieve them and to maintain them. The "basic group-practice unit" is the first and most urgent necessity.

IV. CONCLUSIONS AND RECOMMENDATIONS

Conclusions

1. The present state of general practice is unsatisfactory. Its defects existed before the National Health Service Act, and arise from failure to define general practice and to establish and maintain standards. For several decades general practice has adapted itself to the growth and development of hospital, specialist, and other medical services; but it has not developed concurrently.

2. The National Health Service Act has done nothing immediately or directly to disturb the structure of general practice.

3. The extension of National Health Insurance has increased the load on general practice, and at some points this has caused serious strain or near-breakdown.

4. It is difficult either to confirm or to deny the claims made that this increased load has seriously depressed the quality of medical care. It is very evident, however, that many of the shortcomings attributed directly to the Act are the result of basic weaknesses in general practice which have merely been intensified by the additional load.

5. The claims that new methods for remunerating the doctor have seriously upset the doctor-patient relationship are similarly difficult to confirm or deny, but I found little evidence that they have done so.

6. The indirect effects of the Act on general practice are much more fundamental than the direct effects, around which most of the controversy has centred.

7. The impetus which the Act has given to development of hospital and specialist services has accentuated the defects outlined in (1) above.

8. Through the agency of the regional hospital boards, decisions of policy and principle relating to hospital and specialist services are being taken. No similar decisions are being taken on general practice, and the regional boards' decisions are reached with little or no regard to the problems of general practice.

9. The executive councils responsible for general-practitioner services are fully occupied with day-to-day administration and are not working or thinking at the level of policy.

10. There is little or no coördination of the work of the executive councils and the regional hospital boards. This is not merely an administrative defect: until the executive councils take policy decisions, or have them taken for them, there is nothing of importance to coördinate.

11. For similar reasons, there is very little coördination of general-practitioner services and local-authority personal health services.

12. Hence the future of general practice is largely being determined without deliberate consideration of its problems. It is being determined mainly by the people responsible for hospital and specialist development, and in terms of compensation for recognised, or half-recognised, deficiencies, instead of the correction of these deficiencies.

13. Now that local authorities hold responsibility for health-centre development, one would expect them to be closely interested in the future of general practice. I found little evidence that this was so or was likely to become so quickly. The health centre is being considered primarily as an instrument of local-authority personal health services. Such consideration as general practice is receiving in this regard is more or less nullified by the failure to define its future province and function and to recognise it for what it really is.

14. The best elements of general practice are under attack (e.g., rural practice with cottage-hospital facilities), while the bad elements are being largely disregarded

(e.g., industrial practice). This is the result of the widening schism between the specialist and the general practitioner, and inability to see beyond the practitioner's few but dramatic sins of commission (e.g., surgical) to his many more serious, if less obvious, sins of omission (e.g., missed or mistaken diagnosis).

15. With increased inducements for the young doctor to enter the specialties, and a decreasing scope for work in general practice, the latter is becoming an unattractive proposition. Furthermore, it is difficult for the young doctor with a genuine interest in this field to find a satisfactory way into it. The easiest way is through busy urban practice, and under prevailing conditions this is the least satisfactory way.

16. Unless these conditions are changed, potentially good doctors will be devalued without elevating the quality of practice. Similarly, any hope that financial reward alone will attract good senior practitioners back to these bad conditions is illusory: the good doctor will only be attracted into industrial practice by providing conditions which will enable him to do good work.

17. This question of terms and conditions of practice is of primary importance. The defects of general practice cannot fairly be attributed to the defects of medical education. However inadequate may be the teaching of social and psychological medicine, the teaching of clinical disciplines is good; and bad conditions of practice can, do, and will continue to negate the most conscientious teaching efforts in the newer and more abstruse field of social and psychological medicine.

18. Against this background the few inducements—such as refresher courses with paid locums, and traineeships—are of very little value either as attractions or as a means of raising standards.

19. The present conditions of general practice, and the gloomy outlook for the future, have produced demoralisation in many thoughtful members of the profession. The ideas, ideals, and real dissatisfactions of a considerable number of doctors are not reflected fairly or fully by organised medicine, which has fought so vigorously for what have been called terms of service. With opportunity and encouragement, general practitioners could make a valuable contribution towards planning as well as operating the medical services.

20. If the present trend towards more and more hospital and specialist care continues, it must result in

(*a*) The elimination of general practice as an effective agency of medical care.

(*b*) The substitution of hospital, specialist, public-health, industrial-health, and similar less personal services.

(*c*) The breaking of the one remaining link which gives the patient some continuity of care, and the removal of a focal point for dealing with the non-organic problems—the psychological, economic, and social worries of the people.

Quite apart from human values, it is doubtful whether the policy of concentrating on hospital and specialist care is economically justifiable or even possible, and its hazards will certainly not be lessened by drifting into it.

Recommendations

In spite of this grim analysis of the present position and future prospects, the opportunity to re-establish general practice is still open.

There is real urgency about launching this experimental work; for relatively soon the new patterns of hospital and specialist care will be firmly established and everything will be fitted into them. If that happens it will then be virtually impossible to do very much about general practice.

APPENDICES

I. GENERAL PRACTICE IN SCOTLAND

In the absence of recognised criteria it is very difficult to draw comparisons between practice in one place and practice in another. But after examining practice in Scotland, by methods similar to those I used in England, I came away with the firm impression that, all in all, its quality is higher than that of the English equivalent. I do not claim that the best English practice is not at least as good as the best Scotland can show; but if one can admit an average for the diverse types which go to make up what we call general practice, then in my opinion Scotland is in front.

A DIFFERENT ATTITUDE ?

The attitude of most general practitioners to both local and central authority, as represented by city and county health departments and the Department of Health for Scotland, seemed more reasonable and cooperative than that of English doctors to the corresponding authorities here. Though it could not be said that the relationships were by any means ideal, for the most part they were at least workable.

In England any association, real or imaginary, between my survey work and local or central authority militated against good relations and created obvious suspicion. In Scotland, on the other hand, wherever I went I found I could use either a local authority or the Department of Health as a means of introduction to general practice, without embarrassment and without arousing any serious misgivings. Indeed in one part of Scotland I actually travelled with an officer of the Department, who accompanied me into the various practices I visited; and the doctors were quite as frank in his presence as if I had been alone. In England, on the few occasions when I was introduced by such an officer, I found relations with the doctors strained until I had explained my association with, and established my independence of, officialdom.

The explanation that has been offered me for this difference—that it is merely a matter of the size of the community—is not good enough. The relationships even in country towns in England are often worse than comparable relationships in big cities in Scotland. There is a basic difference in attitude of mind.

This difference in attitude is reflected in other ways. In England discussion with general practitioners on the new health service usually centred on the size of capitation fees, the number of patients on the list, mileage-rates, basic salaries, and so on, until it was steered into professional as distinct from commercial channels. In Scotland I found much more spontaneous interest in professional issues such as the quality of medical service, the relation of general practice to hospital and specialist services, and the development of health centres.

I do not want to give the impression that I am attributing all good to the Scottish doctor and all bad to the English. This is not the case at all. But there is an appreciable difference.

I was similarly impressed by the difference in attitude to general practice (in the two countries) among specialists who had thought at all deeply about general practice. In England I found that many of these specialists had little genuine respect for general practice or the average general practitioner. Much more respect was shown by the corresponding Scottish specialists, and their criticisms of general practice were almost always constructive and sympathetic. Similarly the attitude of representatives of organised medicine towards the new service seemed to me more objective in Scotland than in England.

Industrial Practice

I visited fair samples of industrial practice in both Edinburgh and Glasgow, but saw nothing to equal the kind of thing described in section II of this report. The worst industrial practice I visited in Scotland was at least equal to the "good" English industrial practice I have described.

The surgeries are much the same forbidding kind of places, built to the same two-room patterns and converted from shops or residences; but they are much better equipped. I was never in a surgery where there was not an examining couch; in some there were gynæcological couches; and both of them always seemed to be used for their intended purpose. Sterilisers were usually in evidence, and instrument cupboards seemed to be well kept and reasonably well stocked.

As a rule some sort of an effort was made to keep records. I never saw anything approaching good records, and most of them were poor in the extreme; but at least there was a consciousness of the need for records, and often apology and explanation was offered for their paucity.

In the practices I visited where lists were full (4000), the doctors were extremely busy—far too busy to do good or even satisfactory work—but there was nothing like the congestion or lack of organisation described for comparable practices in England. The discipline exercised by the doctors was notably stronger and sometimes of educational value.

During my periods in various surgeries, a conscientious effort was nearly always made by the doctor to conduct some sort of a useful physical examination. In absolute terms, they were by no means good examinations; they were quick and usually limited to the organ or area of complaint; but they were purposeful and at least eliminated some dangerous possibilities. Patients were not referred to outpatient departments with quite the same readiness and lack of inquiry or thought as in the industrial practices I saw in England.

As a rule there was evidence that the minor laboratory tests which one expects to be done in general practice were in fact done. Certainly urines were tested, whenever I was present, on every occasion that this was indicated. One did not see empty and dirty bottles of Fehling's solution, and test-tubes obviously disused for months or years, lying around the sink-boards. Some of the G.P.s owned and used microscopes, and some did such things as hæmoglobin estimations.

One industrial G.P. I met, who had a full list, had managed to do enough work at his side-bench to earn an M.D.; another was interested in, and working on, the diagnostic significance of the state of the tongue; and a third was making a study of infant feeding. I do not suggest for a moment that some doctors in industrial practices in England are not attempting similar work; but if they are, with conditions as I saw them, they are exceptional men. There was nothing exceptional about the Scottish doctors I have just mentioned: they were ordinary industrial G.P.s to whom I had been referred with no special recommendation; and later, when I took other checks to see whether I was being shown a demonstration sample I could find nothing to suggest that this was so.

It is well known that a considerable number of the less able graduates from Scotland and Ireland migrate to England and find their level in industrial practice here. I have even heard it suggested that the poor quality of Scottish and other immigrant doctors is responsible for the faults of industrial practice in England. This, in my opinion, is quite an untenable thesis. "Good" and "bad" doctors have migrated from Scotland to all types of medical practice in England, the migration being stimulated at times of economic difficulty in Scotland. Many have remained, some to do well in good practices, some to do badly in bad ones. What struck me most was the number of doctors I met who at some period had gone to England (usually into industrial practice) but had been unable to tolerate the conditions and had returned to Scotland. They could all recall the type of thing described in section II of this report, recount their experience of it, and express gratification that it does not exist in Scotland.

The difference in quality of practice is principally one of degree and is by no means absolute. The patterns are the same, but the standards and attitudes are different. There are, however, two major points of contrast between industrial practice in the two countries:

1. In Scotland dispensing practice has never reached the same proportions as in England, and the bottle-of-medicine mentality has not been developed, either by doctor or patient.
2. In Scotland the general practitioner has retained some responsibility (now diminishing rapidly) for midwifery. Because of this (whatever the standards of G.P. midwifery may be) he has remained much more the family doctor than his English counterpart.

Both these facts have materially helped to maintain standards of industrial practice in Scotland.

Urban-residential Practice

In this type of practice the difference between England and Scotland is much less than it is in industrial practice. The surgeries I saw were altogether comparable, as was the nature of the work. The scope of work was no more defined in Scotland than in England, and standards were quite as arbitrary.

As I have pointed out, relations between the G.P., the specialist, and the local-authority doctors favour the Scottish G.P. The retention of some responsibility for midwifery makes family doctoring more of a reality. Also, in the practices I visited, the G.P.s seemed to do more for themselves in minor surgery and elementary laboratory work.

Rural Practice

I took a particular interest in the isolated practices of the north and west, which formed part of the old Highlands and Islands service. For this service enjoys a high reputation internationally as well as locally. It is held up as an example of a well-organised medical service giving medical care of high quality to isolated communities.

I visited about a dozen practices in different parts of the Highlands and Islands. The doctors I met were as fine men as I have met anywhere. They were proud of the service of which they were part; they put up with the harshness of climate and country, and the difficulties of living and working in this rough isolation, because they liked their people and believed in what they were doing. In short they were men of character and integrity.

I make these points with some embarrassment, not to eulogise these doctors, for whom I have the greatest personal respect as men, and certainly not to soften the harsh comments I am about to make, but in order to illustrate a very important point which I have made previously but without the same emphasis. The point is this:

> The continued failure to establish and maintain standards of medical care, and the continued acceptance that general practice is good for its own sake, has deadened the critical faculty and sensitivity of the best of general practitioners, and has resulted in the decline of standards of practice to a dangerously low level.

Almost without exception, the doctors' houses I visited were in a state of bad repair, and some of their surgeries were hopelessly ill equipped. Perhaps I was expecting too much; but I thought that at least they would be well enough equipped to meet the emergencies always liable to arise in rough and rather inaccessible places.

Some, like the English industrial surgeries described previously, had no examining couches.

Once, when I was visiting a doctor in quite a populous area, a patient came in with a history suggestive of appendicitis. After he had been examined by the doctor it was proposed that I should have a look at him. I asked where I could lay him down, and someone went away to the back of the house and dug out a small folding camp-bed which when assembled was about a foot off the ground. We laid the patient down and knelt round him, and after abdominal examination we were still undecided. I asked for a rubber glove or fingerstall with which to make a rectal examination: there were none. I suggested examining a specimen of urine under the microscope: there was no microscope. Finally the patient was sent twenty miles to the nearest cottage hospital, where these things could be done.

On another occasion I was visiting a small maternity hospital in which most of the confinements for quite a large area of country and a considerable number of people were conducted. At this time there was a woman in the hospital suffering from a severe postpartum eclampsia and not responding to simple therapy. We discussed the case and it was suggested that she might go on to an intravenous hypertonic saline drip. There was no saline solution and no intravenous equipment. At this time the hospital was being repainted and refurnished, but not re-equipped.

These are only isolated examples, but they show that standards of practice in an organised general-practitioner service, enjoying an international reputation, can reach low levels.

Here are extracts from a letter written by a doctor who recently acted as locum tenens for one of the practitioners in an isolated part of rural Scotland.

> "The surgery was a back room, which contained a non-functioning stove, a desk, two chairs, and two bookcases. I looked in vain for the examining couch, the tools of diagnosis and minor surgical treatment; they just weren't there. Or rather there were a set of Michel clips tucked away among the cobwebs at the back of a cupboard. They came in useful, when boiled up in a pot on the kitchen stove, two or three times during my stay here.
>
> "There was a large selection of assorted drugs on the shelves, all a little dusty, with one or two large bottles of proprietary remedies on the front shelf. The doctor told me that he usually dispensed these, or else the other medicines he knew how to make. There was a bottle of procaine penicillin two years old and some rather more modern bottles of the sodium salt. This he usually used, 10,000 units daily, since the procaine variety 'was so difficult to inject without using a large needle.' There was some sulphadiazine.
>
> "I searched high and low for case records, X-ray and path reports—there weren't any. Nor were there rubber gloves, fingerstalls, or any item of sterile dressing. . . ."

These comments speak for themselves, need no interpretation, and demonstrate that, even with the best of men, failure to maintain *professional* standards can reach a point where public safety is involved.

Quite a few of the isolated practices I visited could be fairly described in similar terms. Others were better equipped and the standard of work was higher, or appeared to be. However, with one or possibly two exceptions, I saw no practice which could be considered "good" as measured against any reasonable standard. While it would be pleasant to write about these better practices, it would illustrate nothing significant, except perhaps that some individuals, of their own accord, have maintained higher professional standards than others. The important thing is that no minimum standards have been established; that in a service of this kind the work of some practitioners can fall below a minimum standard of safety; and yet that the service and the men who make it up can continue to enjoy a high and widespread reputation.

But I also have another observation to record.

I visited a cottage hospital in one place, which looked after the needs of a community extending over a radius of twenty or thirty miles from the site of the hospital. It was a ten-bed unit and was equipped with X-ray plant and operating-theatre. My visit was made on a Saturday afternoon, and I was greatly impressed by the fact that something over half the doctors who worked in the hospital's area were in attendance there. They were looking at X-ray films, discussing cases, and exhibiting an enthusiasm which was really remarkable. I learned afterwards that some of these men were running practices of the type just described, and the enthusiasm they showed in the cottage-hospital work is very difficult to reconcile with their scientific apathy in their private and individual practices. Or perhaps it really isn't; and perhaps in this simple observation lies the hope for the future of general practice and the betterment of medical services.

Nine of the ten beds were occupied by surgical cases. The one medical case was that of a girl suffering from bacterial endocarditis. Some years previously she had had rheumatic fever with cardiac involvement and she had been under more or less constant attention for several years. Her condition was regarded as hopeless, and the treatment she was receiving was 15,000 units of penicillin daily (she had received this dosage for about a week and was still acutely febrile). Professional interest centred mainly on two or three difficult surgical cases, which had been operated on by the G.P. surgeon during the previous week.

This surgical preoccupation of the G.P. who has access to a cottage hospital is important both for its own sake and in relation to the development of the medical service. It is not difficult to understand why so much interest focuses on surgery—a wholly tangible and satisfying outlet for men working mainly with intangibles and at that to only a low standard. The question is whether this interest can be turned from surgery to the less dramatic problems of medicine. I am sure that much of it can, but it is going to require a great change in the environment of general practice; it will not come about by preaching or teaching, but only by making it possible for the G.P. to do really satisfactory work in the field of general medicine.

Effects of National Health Service Act

In Scotland also I tried to correlate what was happening in outpatient departments with what was happening in general practice. I had no more success than in England; the records just were not available. However, hospital superintendents and consultants usually expressed the opinion that the volume and nature of hospital outpatient work (apart from application for appliances) had not altered substantially since July 5, 1948.

On the sample of practice I saw in Scotland, this could be anticipated; the doctors tried conscientiously to screen their patients before sending them on to the outpatient department, and those who undertook some minor surgery and elementary laboratory work were not talking about dropping it because they were no longer paid for every item of service.

Many doctors spoke of the bigger demand for prescriptions, particularly for small things which the patient would previously have bought for himself. But resistance to these demands was much firmer than I saw in England, and though in some of the larger city practices there was talk of patients changing doctors unless every demand was met, fear of this was certainly not the main factor determining the doctors' conduct.

The direct effects of extending National Health Insurance and of introducing new methods of paying the doctor are the same as for England, but they have caused much less emotional disturbance and accordingly less immediate disturbance of the conduct of doctors and patients.

The problem of differential scales of maternity fees for general practitioners does not arise in Scotland, where doctors have not been reclassified as worth either £5 5*s.* or £7 7*s.* per confinement. This does not mean that there is general satisfaction with the G.P. obstetrician; in fact, this is far from being the case. Many regard antenatal care as a task for the specialist, and favour division of midwifery between the midwife and the specialist obstetrician.

The main point of difference in the Scottish Act, so far as general practice is concerned, is that responsibility for health-centre development is vested in the Department of Health instead of the local authorites. Though the health centre was originally conceived as a large building which would house local-authority services, with, at some stage, some sort of provision for general practitioners, a new concept is developing rapidly. In the newer plans, though the centre serves as the coordinating agency for preventive and curative services, it is primarily a place for medical care and for better general practice.

The indirect effects of the Act are the same for the G.P. in Scotland as in England. His position is seriously threatened by specialist and hospital development unrelated to the development of general practice. His greatest hope for survival lies in a practical policy for health centres. For this reason, and also because he has on the whole maintained better standards than his English colleagues, his position is more hopeful and more defensible.

II. GENERAL PRACTICE IN NEW ZEALAND

The New Zealand experiment in health insurance and medical care has been cited by some as an example of the evils of "nationalised" medicine and by others as an example of its benefits. Indeed it has provided evidence for both sides on almost every contentious issue arising in the new British National Health Service.

Most of the objective reports on the New Zealand service have dealt with administration and planning, and have dwelt on the rather dramatic results of the fee-for-service method of paying the doctor. The attention given to this question of doctors' incomes and patient abuse of a "free" medical service has indeed obscured other important lessons to be learnt from the service, and before going further I must say something about it.

Remuneration

The New Zealand general practitioner can receive his remuneration in one of several ways:

1. Fee-for-service (with or without additional private fee, known locally as a "token" payment).
2. Capitation fee.
3. Salary (in "special area" practices: these are chiefly in remote rural areas and mostly populated by Maoris).
4. Private arrangements with the patient as before the Act was introduced.

To complicate this picture there are two methods by which the doctor can claim his fee-for-service: (1) directly from the State; or (2) directly from the patient, who in turn claims repayment from the State. Moreover any one doctor can use more than one of the methods listed above.

The vast majority of doctors work on the fee-for-service system in one of its forms. It is hardly necessary to point out the abuses to which this system is open and the difficulty of controlling these abuses. Proper control of any large fee-for-service system would require an immense bureaucracy and even then might not be feasible. I have seen one small fee-for-service scheme in the U.S.A. (the Maryland Medical Service for the indigent), which is thoroughly controlled for a population of about 100,000; but even the officials responsible for it are uncertain whether they could maintain their controls for a population greater than a quarter of a million. The questions which at once come to mind are:

(1) How great is the abuse by doctor and patient of the fee-for-service "free" medical scheme?

(2) What are the real effects of this abuse on the standard of medical care?

At its worst the abuse is very great. There are individual general practitioners in cities and large country towns making five-figure incomes on the basis of 7*s.* 6*d.* per item of service. These doctors see great numbers of patients (albeit nothing like the numbers seen in some English industrial practices); they encourage the patient to return with all kinds of trivialities, for repeats of prescriptions, or for courses of dubious injections; and they visit on the slightest indication or perhaps no indication at all.

There is evidence of even worse abuses than these—of doctors collecting "patients'" signatures, for service rendered, where no service has in fact been given. There are stories in plenty of doctors passing the "book" round to collect signatures at a party, of doctors standing a round of drinks in the local hostelry and collecting a fee for service in return, and of other such "amusing" incidents. All these things are possible and many doubtless true.

In ethical terms perhaps the worst offenders are those I call "company" doctors—men with well-established practices who employ juniors on a generous salary and on the basis that they see so many patients per week. This is the ultimate application of legitimate commercial behaviour to a profession we like to consider non-commercial in attitude and conduct. To those who regard medicine as an especially moral and altruistic profession, it is an ethical and moral outrage.

Such conduct is of course indefensible; but, apart from financial considerations (the cost of such behaviour to either the individual or the nation), what matters most is its effect on medical care, both directly on general practice, and indirectly by affecting recruitment to the specialties. Once again, this brings us up against the question of what is good general practice. It also highlights the difficulty of distinguishing between moral and material issues.

For example there is one "company" practice in New Zealand well known because its principal was an early and strong advocate of the service. This practice handles an enormous turnover in terms of numbers of patients and items of service and accordingly brings in an enormous income. It is equipped to handle the volume of work, and the men working in it are "good" men, the net result being that, at least from an organic point of view, the medical service offered by this practice is "good," if considered in relation to the average "good" practice I have visited here. However, the professional attitude to it is one of strong disapproval.

PRACTICE WITH ANCILLARIES

One practice in which I myself worked for a time deserves rather detailed description, because it illustrates many points which need thought.

This was a one-man practice looking after more than 7000 people scattered over a large rural district (some boundaries being as far as thirty miles away from the surgery). The population was mixed Maori and European, some receiving their attention as "capitation" patients and some as "fee-for-service."

The surgery was improvised in quarters above a shop. It was well planned, well equipped, and from a functional point of view very good. There were two consulting-rooms, two examining-rooms (one divided off with a place set aside for minor surgical procedures), a large waiting-room with a side-room equipped with ultra-violet, infra-red and short-wave instruments, a reception and record room, and a side-bench with sink, burners, reagents, test-tubes, and microscope.

Three nurses were employed. They were all trained at least for their general certificate; one had a special pædiatric training. One nurse spent most of her time "on the district": she took and "vetted" most of the calls coming in during the day. The doctor took those patients he chose for himself and any he was asked to see by the nurse, who made a first visit. Another nurse sorted out the patients into those requiring consultation, those needing some minor surgical procedure, and so on, and put them in consulting-rooms or prepared them for examination, dressing, suturing, &c. The third nurse saw principally mothers and children, did some of the antenatal work, tested urines, prepared slides for examination, and looked out records.

The doctor consulted, examined, did an item of minor surgery, and either wrote or dictated his notes immediately afterwards.

The volume of work handled was immense; almost no time was wasted; and yet the human relations between doctor and patient were excellent. The record-keeping was as good as any I have ever seen in general practice and enabled me as a locum to cope with the work without the floundering, searching, and misunderstanding usual in one's early days in a strange practice.

Besides the work in the surgery and the domiciliary visits, this practice handled a great deal of midwifery (I averaged almost a confinement a day during my tenure) and an appreciable amount of general surgery at the local cottage hospital.

Working with a team of nurses in this way is really a modified form of group practice. It grew up in response to demand and certainly not because of the doctor's hunger for a large practice. The overhead was great but by no means incompatible with the income. Patient discipline was intelligent and firm, and there was nothing that could really be called "patient abuse."

There seems something almost unreal about recounting this practice after the type of thing I have been seeing in England, where a higher patient-load has generally resulted in depression of the scope and quality of service rather than any positive endeavour to meet the difficulties by better organisation, individual or collective initiative, or even constructive planning.

This practice I have described illustrates one way of meeting such difficulties. It uses nurses to a level of responsibility I have not seen elsewhere; it maintains a humanism usually lost long before the load of work reaches these proportions; it works to a clinical level equal to the average of the "good" rural general practice in England which has cottage-hospital facilities, and it keeps records as good as any I have seen in general practice. Nevertheless this practitioner has the reputation of running a completely commercial type of practice, because his turnover is so large.

EXTENT OF ABUSES

None of this answers the questions of how great is the abuse by doctor and patient of the fee-for-service scheme and what is the effect of these abuses on the standard of medical care. But it does show that financial abuse is not necessarily synonymous with bad standards of care.

There is a great deal of evidence that many doctors frankly abuse the scheme at the expense of quality of service. The worst of the abuse is in the urban areas, where it is easy to attract large numbers of patients and where they can be encouraged to come back frequently.

One can only hazard a guess at the proportion of doctors who are flagrantly abusing the scheme. Thirty per cent. would probably be a high figure, and in any case the actual number of doctors misconducting themselves in this way is not the important thing, except for the cost involved. What is really important is the fact that some or any doctors can use their position thus, and that this can be known and tolerated both by the public and the medical profession as a whole. Indeed, in a sense, the profession does more than tolerate the abuse; for it actively endorses the fee-for-service scheme which permits and even creates this sort of thing.

This type of misconduct is bound to lower standards of medical care. But, without any definition of general practice and without any criteria of quality, it is impossible to talk in absolute terms about the rise or fall of standards. Generalising very widely I should say that a New Zealand practice where most of the possible abuses are carried out is usually, from the patient's point of view, as satisfactory as a "good average" practice in England. It must be remembered that in these circumstances the quality of the individual doctor may be the sole or primary determining factor in the quality of practice. As anywhere, there are some very bad doctors, and practice is very bad where they are settled; but it is impossible to correlate this with terms of service. The worst practice I saw in New Zealand was one run by a doctor who refused to work any of the State schemes and continued in private contract with his patients, among whom he enjoyed a high reputation.

After ten years in which to observe the advantages and the disadvantages of the service for their patients and themselves, the attitude and thinking of the doctors are still dominated by emotion and finance.

CAPITATION AND SALARY

The doctors working capitation practices are all men who from the beginning favoured a national medical service and as early as 1938 (i.e., before the amending Act of 1941, which introduced the fee-for-service system) agreed to work a national medical service on a basis of capitation. Hence these doctors were philosophically in line with a "State" service, and to that extent they must be considered partisans. But however much this may affect their appreciation and opinion of the service it cannot affect their quality as doctors or the quality of the practices they run. While in New Zealand I was reviewing their practices and not their opinions.

The situation is somewhat different as regards the salaried practices, which cover "special" areas. The most special thing about these areas is that before the introduction of the service there just weren't any doctors working there. Most of these places are in Maori territory, and the absence of doctors before the late '30s was due not to prejudice against Maoris but to the fact that Maoris could not afford to buy medical service. There are also some salaried practices on the west coast of the South Island in isolated and remote rural and mining communities. Before the war some of these practices were filled by displaced persons from Europe, most of whom have done remarkably well. It must also be pointed out that the autonomy of these salaried practitioners is absolute. They are paid a salary, given an area of country with a certain population to look after, and then left to their own devices. (They are of course given car allowances and mileage.) They are not worried by bureaucratic controls, demands for reports, or periodic inspections. This is a state of affairs usually regarded as impossible: salaried practice is assumed automatically to be synonymous with "civil service" or "bureaucracy" or call it what you will.

During my stay in New Zealand I worked in two capitation and two salaried practices and visited some others of both types. All these practices had been operating in their respective ways for at least five years. All of them, in terms of the standards I have witnessed in England, were "very good." None of the presupposed evils of either of these systems of practice were evident. The doctors did not grow lazy or slack, or develop the so-called civil-service attitude: so far from the patients and doctors trying to take advantage of each other, their relationship seemed better than I have witnessed or experienced in other types of practice. In fact, professional considerations took priority over commercial ones.

A COUNTRY PRACTICE

To illustrate some of these points I must relate an experience I had when I took over a practice in a completely Maori area in a remote and beautiful part of the North Island. The area of the practice was very large, the roads were very rough, and the population was about 2500.

I knew quite a lot about the doctor who ran the practice. Before the war he had worked in a city, and he had taken this country appointment for personal reasons in spite of the fact that he was opposed to salaried service or a national medical service of any kind. I thought that under these circumstances I would most certainly see the bad effects of salaried service.

At our first meeting he told me that I would have very little to do, and I jumped to the conclusion that here was an example of how to take it easy on a salary. It transpired that he had announced my coming and had stated that I would be available for all emergencies, for all maternity work, and for three hours a week for general consultation, and, as he put it, "for the curious to come and take a look."

He explained to me that he made these arrangements for all locums, however good or bad, and went on to explain that the majority of *his* patients were *his* dependants and that he did not want me or anybody else disturbing this relationship unnecessarily. This was certainly a change from the usual embarrassed intimation, from doctors (even the most conscientious) operating on a fee-for-service basis, that they usually saw about so many patients a day and please to try to maintain approximately the same figure. In some degree the healthy attitude taken by this doctor was reflected in all the capitation or salaried practices I worked in or visited.

To complete the account I must relate that this doctor was doing a most thorough job with about half the demand on his time usual in a practice looking after this number of patients. He had a very well-equipped surgery and well-kept records, and was doing some independent epidemiological investigation.

I am not trying to claim that in New Zealand salaried or capitation practice has made bad doctors good, or lazy doctors energetic; but I do want to point out that I found no evidence of the converse and no evidence that these ways of remuneration spoil the doctor-patient relationship.

In the most isolated practices I visited in New Zealand I found none so bad, professionally, as those I saw in similar situations in Scotland.

Differences

Considering New Zealand practice in broad terms, and within the framework used to consider practices in England, we can examine the differences.

For the most part the average surgery, urban or rural, is better functionally, and, except for the "good" practices I have seen here, it is much better equipped. I have described one rather extraordinary practice, but there are many where the surgery is planned to meet properly the requirements of a doctor's workshop. The traditional pattern of two rooms—one in which the patient waits and one in which everything else is done—is as much the exception as the rule in New Zealand.

The ordinary surgeries are nothing elaborate or special; they may consist of no more than three rooms instead of the usual two, but from a functional and organisational standpoint this makes a great difference to the doctor and so to the patient. Many doctors have some sort of clerical or nursing assistance at their surgery, and this reflects rather their recognition of the need for this assistance than any undue opulence on their part.

However, the really important differences lie not in organisation or mechanism but in the scope of the G.P.'s work, his degree of responsibility for medical care, and his relationship with hospital and specialist services.

I mentioned previously how some British doctors fear "patient blackmail"—i.e., loss of patients if all their demands are not met. This fear was apparently not shared by the New Zealand doctors, though some confessed that in the early days of the service they used to worry along the same lines. They seem to have learnt, in the few years of "free" service, that their patients respect and accept honest discipline and respond to personal education.

SCOPE AND RESPONSIBILITY

In a way, the New Zealand scheme is the antithesis of the British. In New Zealand the primary responsibility for medical care rests with the G.P.—not because of any deliberate plan but merely because G.P. services have been "free," whereas, outside the hospitals, consultant and specialist services have had to be paid for by the patients. In contrast to the elaborate regional planning which has gone on in England, there has been little or no planning of hospital and specialist services. The New Zealand G.P. has thus been left with a field of responsibility and a scope of work comparable to that of the rural G.P. in England; and there is no doubt, to my mind, that the reaction of the individual doctor to responsibility is one of the chief factors determining the quality of medical care.

Hence the equilibrium between general-practitioner and specialist services is quite different in New Zealand from what it is in Britain. In specialist and also hospital development, New Zealand is relatively backward; but from the point of view of the patient it is a much better place in which to suffer the worries and troubles of ordinary illness.

Nobody knows just what the equation between G.P., specialist, and hospital services should be. Because medical knowledge and technique have advanced so far and so fast, we feel compelled to make available in quantity the higher flights of knowledge and service. In the interests of his own subject, and hence of himself, each specialist and hospital planner feels justified in pushing his own interest to the limit. In this enthusiasm one is prone to lose sight of the patients' interest. In New Zealand, though there are no health centres or any other organised clinics, general practice is highly developed, while hospital and specialist services are relatively poorly developed. Because the balance is so different from what it is in England, I feel sure that an objective study of medical care in New Zealand would provide valuable complementary evidence on what division of function best serves the patient.

I put forward the reactionary thought that the patient, as a person, is better off receiving his medical attention through the undeveloped New Zealand service than he will ever be through any highly developed service depending chiefly on hospitals and specialists.

MIDWIFERY AND FAMILY DOCTORING

Another major difference between general practice in New Zealand and Britain is that the G.P. has retained his responsibility for midwifery. In New Zealand the G.P. is the specialist in normal midwifery. For the most part he does his own antenatal care and his own deliveries, and from my observation he does both of these things conscientiously and well. There are doubtless many bad obstetricians among the G.P.s there, but I came across no really incompetent ones. I never saw a doctor tell a four months' pregnant woman to come back in a couple of months to be "antenataled," as I have seen here, and in nearly all the practices I visited or worked in the antenatal records were well kept.

What I want to emphasise, however, is not the quality of the doctors of either country as midwives, but rather the benefit to general practice, as represented by benefit to the patient and emphasis on "family," which results from the G.P. doing the midwifery.

If "family doctoring" is to mean anything, to be worth anything, and to be an attainable goal, the G.P. must be the midwife. The New Zealand general practitioners for the most part can fairly be called family doctors. They know most of the mothers intimately and they get to know them principally through their attentions during pregnancy; they are proud of the babies they deliver and they watch their development with interest. The G.P.s themselves are the pædiatricians, and it would be very difficult to justify the development of pædiatrics as a specialty, as it is becoming in England and has already become in the United States. All this favours the patient even if it does not favour the future of potential and would-be specialists, and it also favours the national purse.

DIAGNOSIS, SURGERY, AND CHILDREN

The G.P. in New Zealand has open access to the diagnostic facilities of the hospital, both laboratory and radiological. In the bigger cities he is excluded from the larger hospitals as he is here. and accordingly the pattern is the same in that the standards of general care rise as one moves away from the large urban centres; but the differences between the various types of practice in New Zealand are less than in Britain. The urban G.P., never getting inside a hospital, can still do a very high level of diagnostic work. He can have his X-ray and laboratory tests done without referring his patient to an outpatient department or a consultant, and, if he is so minded, he can do a thorough job of investigation before making a referral. On the whole the New Zealand general practitioner screens his patients much more thoroughly than his counterpart in England. and those he sends to hospitals and consultants are much better selected.

Despite the better opportunity to do good work, and the wider range of work undertaken by the general practitioner, the problem of excessive surgery by the G.P. exists in New Zealand as here; and, if the reformers have their way, the patterns of medical care in New Zealand could well follow the English trends. The New Zealand situation should be studied before this happens.

Local-authority services in New Zealand are seldom developed to anything like the level in Britain. On the pro-rata basis, school medical services (though not run by local authorities) are comparable in the two countries, the chief difference being that in New Zealand they are probably quite redundant. because the general practitioners take an interest in, and look after, the children. It would be interesting to know how many children not previously examined by their own doctor are examined by school doctors, and how much significant disorder unknown to the family doctor is unearthed by the school service. On my reckoning and experience it would be very little (eyes may be an exception to this).

Significance of the Experiment

The real significance of the New Zealand experiment does not lie in the problems most commonly discussed —the fee-for-service system and its abuses, the over-prescribing, the under-specialisation, or the failure to develop a planned hospital programme. It lies in the rôle and conduct of the general practitioners.

It should also be realised that the New Zealand plan is not. in fact, a medical plan; it is an economic device to provide a prepaid medical service at the level of general practice. The doctors have not had to adapt themselves to new ways of practice, and they have, to date. been able to control the economics of the situation in their own interests.

The tolerated abuses of the economic plan reflect no glory on any of the responsible parties, least of all on the doctors themselves. The political tolerance of the abuse and extravagance can be interpreted on the one hand as political weakness, or on the other as philosophical strength and patience, born of the hope that, allowed sufficient latitude, the medical profession will exercise its own disciplines and justify the autonomy it enjoys at present. The expressed determination to perpetuate the ways of "abuse," as set down in the report of the Cleary Commission. make this hope look forlorn.

What effects are the easy rewards of general practice having on recruitment to the specialties? Obviously they will attract the commercially minded, but I am sure that the specialists would not profess a desire to have these people in their ranks. The added attraction of quick security must also divert some highly skilled people, who would otherwise pursue a specialty, into general practice. This is a good or bad thing according to one's attitude to general practice. Many specialists, in New Zealand and elsewhere, regard general practice as a kind of prostitution for the man of talent, and so express concern on seeing good men go into general practice. However. from the many young doctors I met in New Zealand and those I have met abroad, I believe that none who genuinely want to pursue a specialty are being wooed away from their desire by quickly and easily attainable wealth.

In this regard, too, the British plan is the antithesis of the New Zealand. Everything here is designed to draw the good man into the specialties. The possibility that the rewards of general practice in New Zealand do in fact help to retain good men in this branch of medicine is perhaps the sole justification for the extravagance, expense, and abuse inseparable from the fee-for-service system.

As regards administration and planning there is nothing to be learnt in New Zealand, except from the school dental services. As regards general practice, within the existing concept of that service, New Zealand could teach us a great deal.

service. There are also some salaried practices on the west coast of the South Island in isolated and remote rural and mining communities. Before the war some of these practices were filled by displaced persons from Europe, most of whom have done remarkably well. It must also be pointed out that the autonomy of these salaried practitioners is absolute. They are paid a salary, given an area of country with a certain population to look after, and then left to their own devices. (They are of course given car allowances and mileage.) They are not worried by bureaucratic controls, demands for reports, or periodic inspections. This is a state of affairs usually regarded as impossible: salaried practice is assumed automatically to be synonymous with "civil service" or "bureaucracy" or call it what you will.

During my stay in New Zealand I worked in two capitation and two salaried practices and visited some others of both types. All these practices had been operating in their respective ways for at least five years. All of them, in terms of the standards I have witnessed in England, were "very good." None of the presupposed evils of either of these systems of practice were evident. The doctors did not grow lazy or slack, or develop the so-called civil-service attitude: so far from the patients and doctors trying to take advantage of each other, their relationship seemed better than I have witnessed or experienced in other types of practice. In fact, professional considerations took priority over commercial ones.

A COUNTRY PRACTICE

To illustrate some of these points I must relate an experience I had when I took over a practice in a completely Maori area in a remote and beautiful part of the North Island. The area of the practice was very large, the roads were very rough, and the population was about 2500.

I knew quite a lot about the doctor who ran the practice. Before the war he had worked in a city, and he had taken this country appointment for personal reasons in spite of the fact that he was opposed to salaried service or a national medical service of any kind. I thought that under these circumstances I would most certainly see the bad effects of salaried service.

At our first meeting he told me that I would have very little to do, and I jumped to the conclusion that here was an example of how to take it easy on a salary. It transpired that he had announced my coming and had stated that I would be available for all emergencies, for all maternity work, and for three hours a week for general consultation, and, as he put it, "for the curious to come and take a look."

He explained to me that he made these arrangements for all locums, however good or bad, and went on to explain that the majority of *his* patients were *his* dependants and that he did not want me or anybody else disturbing this relationship unnecessarily. This was certainly a change from the usual embarrassed intimation, from doctors (even the most conscientious) operating on a fee-for-service basis, that they usually saw about so many patients a day and please to try to maintain approximately the same figure. In some degree the healthy attitude taken by this doctor was reflected in all the capitation or salaried practices I worked in or visited.

To complete the account I must relate that this doctor was doing a most thorough job with about half the demand on his time usual in a practice looking after this number of patients. He had a very well-equipped surgery and well-kept records, and was doing some independent epidemiological investigation.

I am not trying to claim that in New Zealand salaried or capitation practice has made bad doctors good, or lazy doctors energetic; but I do want to point out that I found no evidence of the converse and no evidence that these ways of remuneration spoil the doctor-patient relationship.

In the most isolated practices I visited in New Zealand I found none so bad, professionally, as those I saw in similar situations in Scotland.

Differences

Considering New Zealand practice in broad terms and within the framework used to consider practices in England, we can examine the differences.

For the most part the average surgery, urban or rural, is better functionally, and, except for the "good" practices I have seen here, it is much better equipped. I have described one rather extraordinary practice, but there are many where the surgery is planned to meet properly the requirements of a doctor's workshop. The traditional pattern of two rooms—one in which the patient waits and one in which everything else is done—is as much the exception as the rule in New Zealand.

The ordinary surgeries are nothing elaborate or special; they may consist of no more than three rooms instead of the usual two, but from a functional and organisational standpoint this makes a great difference to the doctor and so to the patient. Many doctors have some sort of clerical or nursing assistance at their surgery, and this reflects rather their recognition of the need for this assistance than any undue opulence on their part.

However, the really important differences lie not in organisation or mechanism but in the scope of the G.P.'s work, his degree of responsibility for medical care, and his relationship with hospital and specialist services.

I mentioned previously how some British doctors fear "patient blackmail"—i.e., loss of patients if all their demands are not met. This fear was apparently not shared by the New Zealand doctors, though some confessed that in the early days of the service they used to worry along the same lines. They seem to have learnt, in the few years of "free" service, that their patients respect and accept honest discipline and respond to personal education.

SCOPE AND RESPONSIBILITY

In a way, the New Zealand scheme is the antithesis of the British. In New Zealand the primary responsibility for medical care rests with the G.P.—not because of any deliberate plan but merely because G.P. services have been "free," whereas, outside the hospitals, consultant and specialist services have had to be paid for by the patients. In contrast to the elaborate regional planning which has gone on in England, there has been little or no planning of hospital and specialist services. The New Zealand G.P. has thus been left with a field of responsibility and a scope of work comparable to that of the rural G.P. in England; and there is no doubt, to my mind, that the reaction of the individual doctor to responsibility is one of the chief factors determining the quality of medical care.

Hence, the equilibrium between general-practitioner and specialist services is quite different in New Zealand from what it is in Britain. In specialist and also hospital development, New Zealand is relatively backward; but from the point of view of the patient it is a much better place in which to suffer the worries and troubles of ordinary illness.

Nobody knows just what the equation between G.P., specialist, and hospital services should be. Because medical knowledge and technique have advanced so far and so fast, we feel compelled to make available in quantity the higher flights of knowledge and service. In the interests of his own subject, and hence of himself, each specialist and hospital planner feels justified in pushing his own interest to the limit. In this enthusiasm one is prone to lose sight of the patients' interest. In New Zealand, though there are no health centres or any other organised clinics, general practice is highly developed, while hospital and specialist services are relatively poorly developed. Because the balance is so different from what it is in England, I feel sure that an objective study of medical care in New Zealand would provide valuable complementary evidence on what division of function best serves the patient.

I put forward the reactionary thought that the patient, as a person, is better off receiving his medical attention through the undeveloped New Zealand service than he will ever be through any highly developed service depending chiefly on hospitals and specialists.

MIDWIFERY AND FAMILY DOCTORING

Another major difference between general practice in New Zealand and Britain is that the G.P. has retained his responsibility for midwifery. In New Zealand the G.P. is the specialist in normal midwifery. For the most part he does his own antenatal care and his own deliveries, and from my observation he does both of these things conscientiously and well. There are doubtless many bad obstetricians among the G.P.s there, but I came across no really incompetent ones. I never saw a doctor tell a four months' pregnant woman to come back in a couple of months to be "antenataled," as I have seen here, and in nearly all the practices I visited or worked in the antenatal records were well kept.

What I want to emphasise, however, is not the quality of the doctors of either country as midwives, but rather the benefit to general practice, as represented by benefit to the patient and emphasis on "family," which results from the G.P. doing the midwifery.

If "family doctoring" is to mean anything, to be worth anything, and to be an attainable goal, the G.P. must be the midwife. The New Zealand general practitioners for the most part can fairly be called family doctors. They know most of the mothers intimately and they get to know them principally through their attentions during pregnancy; they are proud of the babies they deliver and they watch their development with interest. The G.P.s themselves are the pædiatricians, and it would be very difficult to justify the development of pædiatrics as a specialty, as it is becoming in England and has already become in the United States. All this favours the patient even if it does not favour the future of potential and would-be specialists, and it also favours the national purse.

DIAGNOSIS, SURGERY, AND CHILDREN

The G.P. in New Zealand has open access to the diagnostic facilities of the hospital, both laboratory and radiological. In the bigger cities he is excluded from the larger hospitals as he is here, and accordingly the pattern is the same in that the standards of general care rise as one moves away from the large urban centres; but the differences between the various types of practice in New Zealand are less than in Britain. The urban G.P., never getting inside a hospital, can still do a very high level of diagnostic work. He can have his X-ray and laboratory tests done without referring his patient to an outpatient department or a consultant, and, if he is so minded, he can do a thorough job of investigation before making a referral. On the whole the New Zealand general practitioner screens his patients much more thoroughly than his counterpart in England, and those he sends to hospitals and consultants are much better selected.

Despite the better opportunity to do good work, and the wider range of work undertaken by the general practitioner, the problem of excessive surgery by the G.P. exists in New Zealand as here; and, if the reformers have their way, the patterns of medical care in New Zealand could well follow the English trends. The New Zealand situation should be studied before this happens.

Local-authority services in New Zealand are seldom developed to anything like the level in Britain. On the pro-rata basis, school medical services (though not run by local authorities) are comparable in the two countries, the chief difference being that in New Zealand they are probably quite redundant, because the general practitioners take an interest in, and look after, the children. It would be interesting to know how many children not previously examined by their own doctor are examined by school doctors, and how much significant disorder unknown to the family doctor is unearthed by the school service. On my reckoning and experience it would be very little (eyes may be an exception to this).

Significance of the Experiment

The real significance of the New Zealand experiment does not lie in the problems most commonly discussed —the fee-for-service system and its abuses, the over-prescribing, the under-specialisation, or the failure to develop a planned hospital programme. It lies in the rôle and conduct of the general practitioners.

INCIDENCE OF TUBERCULOSIS IN NURSES IN A DUBLIN HOSPITAL AND THE STEPS TAKEN TO REDUCE THIS

GEOFFREY BEWLEY
M.D. Dubl., F.R.C.P.I., F.R.C.S.I., D.P.H.
PHYSICIAN, ADELAIDE HOSPITAL, DUBLIN

DURING the last twenty years a great and increasing interest has been taken in the incidence of tuberculosis in nurses and the methods to be used in an endeavour to reduce this. It is now clearly recognised that nurses, even in general hospitals where tuberculosis is rigidly excluded, run a far greater risk of developing this disease than do comparable members of the general population.

SOME COMPARISONS

It is surprising how different are the figures given by different authors for the incidence of tuberculosis in nurses (table I).

One reason for this difference is that some authors only include cases of tuberculosis which occur during the training period, whereas others follow up their nurses for years after they have completed their training. Heimbeck does this and includes in his numbers one nurse who developed phthisis 18 years after starting her training. I have done the same and include one nurse who developed tuberculosis 9 years after starting. Another reason for the difference in the incidence of the disease is that some surveys were started earlier than others and so show rather higher figures, since there has been a slow but steady decline in the incidence of tuberculosis in almost every country of the world during the last 50 years. A third reason is that some races are more prone to develop tuberculosis than others. This is well brought out in the Prophit survey (table II).

TABLE I—INCIDENCE OF TUBERCULOSIS IN NURSES

Country	Author	Nurses studied	Cases of tuber-culosis	Inci-dence %
U.S.A. ..	Ross (1930)	800	48	6·0
,, ..	Shipman and Davis (1933)	143	9	6·3
,, ..	Geer (1934)	934	42	4·5
,, ..	Ulmar et al. (1936) ..	1000	21	2·1
,, ..	Amberson (1941)	885	61	6·9
,, ..	Badger and Ritvo (1941)	510	21	4·1

TABLE II—INCIDENCE OF TUBERCULOSIS IN DIFFERENT GROUPS

Group	No. examined	Cases of tuberculosis	Incidence %
Prophit Survey, 1931–43			
Group A hospitals ..	1241	24	1·9
,, B ,, ..	2692	47	1·8
Irish and Welsh nurses	937	41	4·4
Adelaide Hospital, Dublin, 1920–47			
Irish nurses	501	43	8·6

Group B hospitals had no tuberculosis wards and did not accept chronic or advanced cases, while Group A hospitals took in all classes of patients, including advanced cases of phthisis. The Irish and Welsh nurses worked in both groups of hospitals but their figures were separated from those of the English and Scottish nurses who worked in these hospitals and were given separately. The table shows clearly that the Irish and Welsh are more susceptible to tuberculosis than are the English. Similarly in America, and even more decidedly, the negro is more susceptible than the white.

MEASURES ADOPTED

Even allowing for increased susceptibility in our nurses the figure of 8·6% at the Adelaide Hospital is very high and is worth considering further. In 1920 no specific precautions were taken to prevent infection of nurses with tuberculosis. As the years went by it was realised that general measures were insufficient; and in 1932 it was decided to X ray all nurses before accepting them for training. In 1938, patients with open phthisis were excluded from the general wards and transferred to isolation wards. This does not mean that there is no danger of infection in the general wards, for unrecognised cases of phthisis are admitted from time to time into surgical or medical wards. Some of these are recognised later but not all. Cases of surgical tuberculosis with discharging wounds are also a source of danger. In 1939 we decided to do a tuberculin-test (Mantoux) on all probationers, to repeat it on negative reactors every 6 months, and to take further X-ray films of the lungs of those whose tuberculin-reaction changed from negative to positive. In 1948 we decided to X ray all nurses in the hospital every 6 months and to inoculate with B.C.G. all probationers who were Mantoux-negative on entry. In table III our nurses are grouped according to three time-periods; and I have put in some figures relating to medical students of the hospital for comparison. This table reflects, I think, the downward trend of the incidence of tuberculosis which has been observed in Ireland.

TABLE III—TUBERCULOSIS IN NURSING STAFF AND MEDICAL STUDENTS AT THE ADELAIDE HOSPITAL

Period	Total	Cases of tuberculosis	Died
Nurses			
1920–38	312	29 (*9·0%*)	4 (*1·25%*)
1939–47	189	13 (*6·87%*)	1 (*0·5%*)
1948–49	47	1	0
Medical student			
1920–38	350	11 (*3·2%*)	0
1939–47	147	5 (*3·4%*)	0

TABLE IV—MANTOUX-POSITIVE AND MANTOUX-NEGATIVE ENTRANTS COMPARED

Entrants	Total	Tuberculosis	Died
Nurses (1939–49)			
M –	93	6 (*6·4%*)	0
M + ...	143	8 (*5·6%*)	1
Medical students (1939–47)			
M –	27	1	0
M + ...	72	4	0

It is, however, of greater interest to consider the difference, in the incidence of tuberculosis, between those nurses who are Mantoux-positive on admission, and those who are Mantoux-negative (table IV). It is worth while comparing these figures with those of the Prophit survey (table V) and of Heimbeck (table VI.)

TABLE V—ENTRANTS IN THE PROPHIT SURVEY AND THE ADELAIDE HOSPITAL COMPARED

Entrants	Total	Tuberculosis
Prophit survey (1934–43)		
M – Group A hospitals ..	229	8 (*3·5%*)
M – Group B ,, ..	491	19 (*3·9%*)
M – Irish and Welsh ..	250	21 (*8·4%*)
M + Group A hospitals ..	1012	16 (*1·6%*)
M + Group B ,, ..	2201	28 (*1·3%*)
M + Irish and Welsh ..	687	20 (*2·9%*)
Adelaide Hospital (1939–49)		
M –	94	6 (*6·4%*)
M + ...	142	8 (*5·6%*)

It will be seen that our figures of tuberculosis in Mantoux-negative nurses are comparable with those of the Irish and Welsh nurses in the Prophit survey.

In table VI our figures for Mantoux-negative nurses again compare favourably with those of Heimbeck. The incidence of tuberculosis in nurses who were Mantoux-positive on entry is distinctly higher than is found in either of these tables but statistically this is of no significance, and is explained by the small numbers of nurses in my survey.

COURSE IN THE NURSES AFFECTED

The 14 nurses who developed tuberculosis may be considered more fully. The lesions in those who were Mantoux-negative on entry are shown in table VII.

TABLE VI—NURSES AT ULLEVAL HOSPITAL (HEIMBECK 1948) COMPARED WITH THOSE AT THE ADELAIDE HOSPITAL

Group of nurses	Total	Tuberculosis	Died
Ulleval			
Nurses in training			
M – entrants	284	97 (*34 2%*)	10 (*3·5%*)
Given B.C.G.	501	35 (*7·0%*)	2 (*0·4%*)
M + entrants	668	22 (*3·3%*)	0
Trained nurses			
M – entrants but became M + ...	178	8 (*4·5%*)	2 (*1·1%*)
Given B.C.G.	377	7 (*1·9%*)	2 (*0·5%*)
M + entrants	504	13 (*2·6%*)	1 (*0·2%*)
Adelaide Hospital			
All nurses			
M – entrants	94	6 (*6·4%*)	0
M + entrants	142	8 (*5·6%*)	1 (0·7%)

Of these six, five had their primary complex about 6 months after starting training.

One nurse, who had erythema nodosum, was sent home for 3 months' rest but foolishly took a job as companion and developed a pleural effusion forthwith. Two others developed effusions 6–8 months later but recovered and were fit for work within a year. Another two developed a slight infiltration into one lung after a longer interval, had 12 and 15 months' rest, and then returned to complete their training; all 5 have remained well since.

Nurse 6 had a cough fairly continuously from the start of her training but remained Mantoux-negative and radiologically normal for $2^1/_2$ years. She then became Mantoux-positive with an attack called "flu" and developed phthisis 6 months later. She was in Forster Green Sanatorium and had an artificial pneumothorax (A.P.) induced. She is still getting refills and is very well and married. It is now almost 9 years since she started her training.

TABLE VII—NURSES MANTOUX-NEGATIVE ON ENTRY

Nurse	Signs at time of primary complex	Months from start of training	Tuberculous infection	Months from start of training
1	Erythema nodosum	5	Effusion	5
2	Dry pleurisy ..	6	,,	14
3	Nothing	3–12	,,	16
4	"Flu"	7	Phthisis	31
5	Nothing	1–9	,,	41
6	"Flu"	30	,,	36

Of the eight Mantoux-positive nurses (table VIII) two developed phthisis after they had completed their training and had left the hospital.

Nurse 9 had nearly completed her training when she developed a cavity in one lung; an A.P. was induced and she went to Forster Green Sanatorium. There she did well and was discharged, keeping up her A.P. She then developed an empyema with a mixed infection and subsequently died.

Nurse 10 had a minimal infiltration which appeared after 14 months; she was away for 6 months and apparently got completely well; when she had almost finished her training she developed a tuberculous kidney and had a nephrectomy, but is now well.

Nurse 11 had a doubtful infection previously and should never have been accepted for training; after 9 months she had a recurrence but was so well 19 months later that we allowed her to start work in our convalescent home; she broke down again a year later and was in Forster Green Sanatorium.

TABLE VIII—NURSES MANTOUX-POSITIVE ON ENTRY

Nurse	Tuberculous infection	Mos. from start of training	Later history
7	Phthisis	72	Married
8	,,	57	Off work 12 mos.
9	,,	42	Sanatorium; A.P.; married; empyema; died
10	,,	14	Off work 6 mos.; completed training; tb. kidney, 48 mos. after start
11	,,	9	Doubtful earlier infection when at school; off work 19 mos.; recurrence 12 mos. later
12	Effusion	35	On sick leave
13	,,	5	Erythema nodosum 1 month after entry
14	Miliary	2	Streptomycin; sanatorium; to take up nursing again after 20 mos.

Nurse 12 was Mantoux-positive to 1/100 on entry. Almost three years later she had a feverish attack with severe headache and pleuritic pain in her chest; an X-ray examination showed slight effusions at her left base and right superior fissure, which cleared up in a few days. During this illness her Mantoux test became positive 1/10,000, and I believe that her pleurisy was tuberculous.

Nurse 13 was a very puzzling case. She was Mantoux-positive to 1/10,000 on arrival and one month later developed erythema nodosum. She had no evidence of streptococcal or other infection which could account for the erythema nodosum, and I believe that she was undergoing her primary infection at the time of starting. She developed a pleural effusion 4 months later.

TABLE IX—MANTOUX REACTIONS IN NURSES AND STUDENTS FROM DIFFERENT BACKGROUNDS

Subjects and their origins	Total	M +	M –
Adelaide Hospital		%	%
Nurses, Ireland	236	60·2	39·8
Medical students, Ireland	99	72·7	27·3
Prophit survey			
Nurses, England, Rural	310	80·0	20·0
Nurses, England, Urban	3025	82·0	18·0
Nurses, Wales, Rural	118	65·3	34·7
Nurses, Wales, Urban	176	80·7	19·3
Nurses, Ireland, Rural	330	65·2	34·8
Nurses, Ireland, Urban	215	81·4	18 6
Medical students, England, Rural	104	85·6	14·4
Medical students, England, Urban	1260	85·6	14·4

Nurse 14 was also very puzzling. She was not looking well 2 months after starting training although she felt perfectly well and was full of energy; a routine X-ray examination suggested a miliary infection of the upper parts of both lungs. She had no temperature at any time and after the first few days looked and felt perfectly well. She was treated with streptomycin and transferred to a sanatorium in Wales; she remained extremely well and her lungs cleared completely. She is coming back to us to complete her training.

From 1939 to 1949, 236 nurses have started training in the Adelaide Hospital and of these 142 were Mantoux-positive on entry and 94 Mantoux-negative. It is of interest to compare these figures with those of some of our medical students and of the Prophit survey (table IX).

I have not been able to divide our nurses into those who come from rural and urban districts, but the majority are rural in origin. If our figure for Mantoux-negative nurses is compared with that of the Prophit survey for Irish nurses, combining rural and urban nurses into one group, there is a significant difference—39·8% in this series as against 27·0% in the Prophit survey—for which I can offer no explanation.

TABLE X—TUBERCULIN REACTIONS ON JOINING THE ADELAIDE HOSPITAL AND SUBSEQUENTLY

Reaction as entrants and later	Nurses	Medical students
M + ...	142	72
M − became positive during training ..	50	15
M − no conversion ; training uncompleted ..	21	8
M −, and at end of training	1	4
M −, and given B.C.G...	22	..
	236	99

Of the 94 Mantoux-negative nurses 50 have become Mantoux-positive and only one nurse remained negative to the end of her 4 years' training period ; 21 are still in training or have left hospital before they were qualified, and 22 had B.C.G. (table X).

It is generally agreed that the first year after the conversion of the Mantoux-test from negative to positive is the period in which there is greatest likelihood of developing tuberculosis. We have tried to send our nurses home for 3–6 months' rest as soon as they develop their primary complex. In practice however many of our nurses have gone through this stage without any disturbance to their health whatsoever, and conversion has only been recognised by a subsequent routine Mantoux test (table XI).

TABLE XI—SYMPTOMS OF PRIMARY COMPLEX IN NURSES AND MEDICAL STUDENTS AT THE ADELAIDE HOSPITAL

Symptoms	Nurses	Medical students
Erythema nodosum	9	0
Feverish attack, " flu "	9	3
Pleurisy—dry	3	0
,, —with effusion	0	1
Phlyctenular conjunctivitis ..	1	0
No symptoms	28	11
Other symptoms	0	0
	50	15

It is of interest that we have had three cases of erythema nodosum amongst our nurses who were Mantoux-positive on entry. One whom I have already mentioned had this condition 1 month after arrival and developed a pleural effusion 4 months later. The other two had it 23 and 38 months after starting training and both had concomitant sore throats.

ROUTINE USE OF B.C.G.

Before candidates are called up we ask permission from their parent or guardian to give them B.C.G. if they are Mantoux-negative, and in no case has this been refused. Since the beginning of 1948 we have given the vaccine to all who were Mantoux-negative *on arrival*, and we have to thank Dr. Dorothy Price and her associates for enabling us to do this. They are Mantoux-tested as soon as they arrive in the hospital and if negative to 1/100, are given B.C.G. *immediately*. This takes a week, and since our nurses are in the preliminary training school and not on the wards for 8 weeks, they have 7 weeks after the inoculation before coming into contact with any case of tuberculosis. Six weeks after the inoculation we retest each nurse with a strength 1/100 and about half of them are then positive. By the end of 3 months most of the nurses have positive Mantoux reactions, but one nurse is still negative at the end of 1 year. *Results have been as follows :*

Inoculated with B.C.G.	22
Left hospital within 6 weeks	1
Conversion in 6 weeks	10
Conversion between 6 weeks and 3 months	6
Conversion in 3–6 months	3
Mantoux-negative after 1 year	1
Mantoux-negative after 3 months	1

The last nurse has only been in hospital for 3 months and I hope will be found to be positive at her next Mantoux test. The nurse who is still negative is an example of the cases where B.C.G. is given but fails to produce any primary complex. One of our medical students had a similar failure and had a second inoculation with B.C.G. but again there was no conversion of the Mantoux reaction.

We have tried for some time to keep Mantoux-negative nurses out of the wards where there are tuberculous cases, but this is very difficult to manage in a small hospital where patients are sometimes found to be suffering from phthisis as well as the condition for which they were admitted. The use of B.C.G. and the conversion of almost all Mantoux-negative nurses to positive overcomes this serious difficulty. Actually it is probably an advantage for nurses to have some contact with tuberculosis after they have had B.C.G. and become Mantoux-positive, since the encounter reinforces the degree of immunity produced by B.C.G. Half of these nurses have become Mantoux-positive to a dilution of 1/1000 tuberculin some months after they were positive to 1/100 only ; and this, I believe, is due to repeated absorption of small numbers of tubercle bacilli by all nurses working in hospitals, and indeed by most members of the general population. Occasionally nurses and others receive a larger dose of organisms, and, if Mantoux-negative, may easily develop symptoms.

One of our nurses on retesting 6 weeks after receiving B.C.G. gave a rather doubtful reaction to a strength of 1/100 Ten months after the inoculation she was very strongly positive to 1/1000, her area of infiltration being over 3 in. in diameter and her whole forearm swollen from elbow to wrist. At the same time her three B.C.G. nodules swelled up and became red. She felt ill and had to be kept in bed for a week and then given a period of sick leave.

It is far too soon to try and draw any conclusions about reduction in the incidence of tuberculosis among our nurses through the use of B.C.G. and the various other methods I have mentioned. But we feel that it is of the greatest importance and a matter of urgency to do everything within our power to lessen the danger of this infection to our nursing staff.

"... Ninety-eight more millions are required for the Health Scheme, and one more youth is to be hanged for murder. ... Both suggest that the health, moral and physical, of this nation is not what it should be. ... In both cases the trouble may be due to too much cure and not enough prevention ; *hanging and flogging*, pricking and drugging—instead of enlightenment. It would be cheap for this country to spend fifty million a year in films to teach the people how not to need the doctor, and how not to put so much hope in the medicine bottle and the prick, by spreading better notions about cleanliness, the constitution and working of the human body, diet, and the rearing of children. It would be not only cheap but charitable as well to spend another fifty million to prevent youths from being flooded with crime images in cinema halls by giving them better films."—S. de MADARIAGA, *Manchester Guardian*, March 17, p. 6.

SOME CAUSES OF THE CARNAGE ON THE ROADS*

FROM A CORRESPONDENT

MANY remedies have been advocated for the carnage on the roads, but comparatively little has been written on the more basal question of ætiology. It is customary to blame the car-driver and to demand a more stringent driving test or heavier penalties against sinners. As doctors, we should look more closely at other removable causes such as bad lighting, lack of road signs, and the many hazards of the highway. Let us take two examples:

Lighting.—A man is driving his car westward from Shepherd's Bush to High Wycombe. From Westway until he reaches Horn Lane he glides along a safe well-lighted double track. At that spot, *without warning*, he is suddenly plunged into semi-darkness on a dangerous winding single track until he reaches Park Royal. The lighting then improves, but the single track threatens him as far as Greenford. This piece of highway treachery is unfair to the driver and dangerous to the public.

Road Signs.—Again, the driver who has only a bowing acquaintance with the main roads leading out of London gets little help from the authorities. From time to time he may be told the destination of roads that slink away to the right or left, but he is never by any chance given the name of the street along which he is actually travelling. Now and again, at great risk to himself and other road users, he must squint up at some building in the hope of deciphering a street name. In cities like New York the authorities tell him at every cross-roads (*a*) the name of the street on which he is driving and (*b*) the name (or number) of the cross street. He is thus able to keep his eye on the road and drive safely.

THE DRIVING TEST

We ought also to call for an impartial examination of the driving test itself. There is a deplorable lack of statistical information on the examiners' findings, though we are told that the rate of failures under test conditions is about 36%. The regulations were introduced in a praiseworthy attempt to improve standards of driving, and to increase the margin of safety on the roads. Are they achieving their object? Is the system helpful to applicants as an education, or is it merely becoming a tyranny of tricks and rules? In the car-driving test as it stands today the victim suffers many disadvantages. (1) He is seen by only one examiner, for a very short period, perhaps in a strange town. (2) He is probably nervous and ill at ease, and therefore liable to errors that he would not normally commit. (3) He has not previously had an opportunity of driving alone, and so lacks the confidence of personal experience. (4) If he fails he must either not drive at all or return to the leading-strings for a whole month—or risk a fine of 10*s.* and a month's imprisonment. And lastly (5), the examiner knows nothing about the candidate's background or training.

No doubt the Ministry of Transport has conducted operational research into these matters, and it would be useful to know something of the results. The following points would be instructive:

1. The proportion of applicants passed at each attempt, area by area.
2. A comparison of the results over several years.
3. An analysis of the results of first and subsequent tests with reference to the candidate's age, sex, and possibly occupation.
4. The main reasons for failure put forward by examiners.
5. The pass-rate at different times of the day and on different days of the week.
6. The difference, if any, between wet days and fine days.
7. The results of presenting the same candidate to various examiners.
8. A psychological study of the success or failure of applicants, in relation to simple personality features.

Psychology of the Driver

An investigation of the candidate's personality might be particularly interesting. Thus, broadly, one would expect the extrovert to make a good showing at his first test. He concerns himself primarily with objects, facts, and persons in his immediate environment, and he tends to be practical in affairs. On the other hand, he soon ignores the lessons learnt, because he is essentially opportunist. He shows no great concern for others. The introvert is more concerned with his own impulses than with direct response to varying outward sensations. He shows up badly, as a rule, in "snap" tests, but his discrimination and judgment are sounder than these would suggest.

A psychological study would be misleading without an exploration of the broad no-man's-land between normality and the neuroses. The obsessional may do splendidly in an examination, if he concentrates for the time being on the object of his desire; but in the long run he will be unreliable as a driver. The anxious type, on the contrary, almost invariably does badly under test conditions but is more likely to be conscientious and considerate on the road. Unfortunately the anxiety tends to be progressively exaggerated by repeated examinations, and the unhappy victim is deprived by the regulations of his one chance of success—an opportunity to gain confidence through practice by himself.

The Tenderfoot

A further question we should ask is simply this: what proportion of automobile accidents are associated with recently tested motor-car drivers? The figures might be further broken down and analysed.

LIGHT-FLASHERS

It is curious that apparently no-one has referred to the new nightmare of discourtesy—light flashing at cross-roads in the city. The other day we had to attend medically to a woman who had collided with a lamp-standard on the pavement. She had been temporarily blinded by a selfish driver who persisted in flashing his headlights on and off to save himself the trouble of slowing down. This cruel and dangerous malpractice is on the increase, and should be forbidden.

Public Health

Mortality in Northern Ireland

IN Northern Ireland during 1949 the infant mortality (45 per 1000 live births), the maternal mortality (1·27 per 1000 live births), and the death-rate from tuberculosis (59 per 100,000) were the lowest ever recorded. The birth-rate, at 21·4 per 1000 population, showed a small decrease but was still above the average recorded for the ten years before the war. Last year 24 persons died of cancer for every 10 who died of tuberculosis; but there has been no increase in deaths from cancer in the past seven years.

Q Fever in Germany

The Office of the Surgeon-General, U.S. Army, has reported that 90 civilian cases of Q fever have occurred at Zusenhausen (population 1500), near Heidelberg. Most cases have been mild, although 1 death has been reported. The diagnosis has been confirmed by the Fourth Medical Laboratory, Heidelberg.

The source of the epidemic has not yet been ascertained by the German health agencies. Presumably Zusenhausen represents a new area in Germany for this disease.

In England Now

A Running Commentary by Peripatetic Correspondents

As a surgeon I'm finding life very hard these days, not because of the growing amount of work but because almost every day I have to operate on somebody who only a year or two ago would have been labelled inoperable and left to die in peace—cases of carcinoma of the pancreas or stomach, of bleeding peptic ulcer, and so on. Most of them are referred from other hospitals or departments. What with transfusions and penicillin quite a few do recover; but of course some still die. Nowadays we are expected to cure them all; and when one dies it's a severe blow to my reputation and to the department which referred him to me—this patient whom no-one would have dreamt of operating on a couple of years ago. The patients who do well just disappear and are more or less forgotten; but those who die are remembered, and whenever there is a death in my wards it takes me a couple of days to recover—to get back into full mental working order. I am in a state of constant anxiety; and I can see no end to it. I can't blame anyone but myself and my vanity in concentrating on the apparently hopeless cases. I wish now that I had specialised in pilonidal cysts or hammer toes.

* * *

At Olympia the Ideal Home Exhibition, which is open until April 1, offers something for almost every domestic taste. The furniture on view ranges from genuine and imitation antique to the most modern, which now includes a set of panels and fittings that can be joined up into different articles of furniture. There is a French exhibit showing a room prepared for a banquet—a rather too stimulating sight. There are many fascinating fireplaces, most with real fires burning. The mass of electrical household items is incredible; there seems to be nothing that cannot be done by electricity except setting the table and making the bed. The cooking stalls are reminiscent of displays of magic, now that pressure-cookers have reduced the time of cooking from hours to minutes and seconds. The W.V.S. have forceful lessons to teach about the safety of children in the home. Mr. Cube is there, complete with a model West Indian plantation. Cocoa is represented, and New Zealand has sent over a typical house. In the eighteen gardens spring flowers abound, flowering shrubs are everywhere blossoming, and the bulbs are magnificent; and how delicious it is to smell carnations and roses in March. With its demonstration of apprentices learning carpentry and other home-like occupations, even the Army does not disturb the idyllic atmosphere.

* * *

When I rang up one of the London teaching hospitals the other afternoon—it was a trivial errand, just to ask a friend of mine on the house to play golf at the week-end—I reflected that the reputation of a hospital mainly depends not on the senior surgeon or even the secretary of the management committee, but on the girl who answers the telephone.

After a minute or two's ringing a voice snapped "Golgotha Hospital." "I'm so terribly sorry to trouble you," I said in my most deprecating manner; "I wondered if I might speak to Mr. Forcep?" But the voice had vanished as unaccountably as Ariel's music. In a couple of minutes she returned and cut short my abashed request by barking, "You want surgery." I was wondering if she had discerned my deviated septum over the wire when a rough male voice announced, "Surgery 'ere. Wotcherwant?" "Could I please speak to Mr. Forcep?" "Oozat?" "Mr. Forcep." "Nevereardofim. Is 'e a stoodent 'ere?" I established the bona fides of my friend and was told to 'oldon. There followed the depressing sound of the receiver being abandoned on the desk, which I recognised as the death-rattle of constructive inquiry. When three or four silent minutes had passed I reached for THE LANCET and began reading the leader pages. I was well into the annotations when a fresh superior young male voice sounded in my ear. "Do you want the stools straight away?" he asked. "I'd better send them now. They'll be no use to you if they're not warm." I told the unknown I didn't want his stools. "Aren't you the path. lab.?" he demanded crossly. I explained I wasn't. "Oh damn!" he said. I had started on the original articles and was suffering severe ischæmic pain in my right arm when a sweet female voice told me abruptly, "Your wife is as well as can be expected and you may visit her tomorrow between the hours of two and four." "Thank you," I said humbly, being by now grateful for any attention, however irrelevant. Five minutes later the rough voice snarled, "'Is board's marked 'Out.' Bin marked 'Out' fer weeks," and he crashed down the receiver. Luckily it was only Wednesday, so I sent a post-card.

Hospital telephone girls have a lot to put up with, of course, what with irate surgeons and bare inquiries like "How's our Ada to-night?" But they could profitably study standing orders for telephonists at, say, a West End shop. It's as nice to hear a pleasant voice say immediately, "Selfishes, good morning," as it is to get an unexpected smile from a pretty girl on the bus. Why, even if you ring PAD 7000 a delightful young soprano exclaims "Paddington Station, may I help you?" Try it and see. But my favourite call is to a ladies' hairdressers round the corner which I discovered one day with a lucky wrong number. I'll spend tuppence any time just to hear that delicious voice say eagerly, sweetly, but with the inflection that infers she means business: "Madame Pompadour, at your service."

* * *

Shame on my friend of March 11 that he should write of Hornibrook's system of abdominal exercises in a spirit of ribaldry. He has only himself to blame if his abdomen is not less protuberant than before. A protuberant belly cannot be made to shrink, any more than Rome could be built, in a day. These exercises are unusual, grotesque, even suggestive; but their potency as a remedy for simple constipation or a corpulent abdomen (not generalised obesity) cannot be denied.

When I was a surgical dresser, my chief found in one of his beds a woman admitted for—among other things—surgical treatment for constipation. This surgeon seemed not to like the idea of such an operation and agreed with alacrity that we should try the effect of Hornibrook's exercises. The woman left the hospital ten days later having daily spontaneous bowel movements. She wrote to me for years afterwards that this happy state of affairs still obtained and that she still followed the ritual. She was the most grateful patient I have known. I recall a man with a corpulent abdomen who practised the exercises for a few minutes daily and after three weeks could insert his hand sideways between his abdominal wall and his formerly well-fitting trousers.

Most people get the result they want but in the end give up the exercises, preferring to spend the few minutes in bed and put up with their symptom. Those faithful ones who persevere do not "have nightmares featuring a fiend answering to the name Hornibrook."

* * *

The family were discussing that poor lad who could not stop sneezing. (By the way, what happened to him in the end? I hope, since we did not see anything more in the papers, we can assume that the general press rule holds: Bad news is news; good news is not.) Well, the children wanted to know what other things could go on more or less for ever. Hiccups was obviously the first, and then squinting and nose-bleeding. It is our custom to discuss all non-drawing-room subjects frankly but politely. Thus, the passage of flatus is known as "bottom-talking." We had previously been into the possibility of articulation per anum. So of course we were asked whether people are ever unable to stop their bottom talking. "But," said Jeremy, "how on earth would they write about it in the newspapers?" "Luckily," I replied, "there is one weekly newspaper which has a special column for such strange matters, called *In England Now.*" The children thought this over for some time. Then one of them asked, "What will they do if the first person whose bottom won't stop talking is a Frenchman?" "Let us," I suggested, "adopt the maxim of Mr. Asquith, and wait and see."

Letters to the Editor

VAGOTOMY FOR ULCERATIVE COLITIS

SIR,—Your annotation of Jan. 14 raises the question of the therapeutic effectiveness of vagotomy in ulcerative colitis. This is open to much debate and discussion. In the first place, there is no evidence at the present time that the vagus innervates the colon. Apparently vagal fibres stop at the ileocæcal valve. The impulses from the vagus nerve must be mediated through Auerbach's and Meisnner-Billroth's plexuses in the right half of the colon up to the ascending limb of the splenic flexure. These plexuses are continuous with those in the ileum. The vagus plays only an indirect rôle in ulcerative colitis. The emotions causing this disease are primarily transmitted over the sacropelvic nerves.

What vagotomy does do is to slow down peristalsis of the small intestine; and it prevents such a high titre of unattenuated or inactivated pancreatic enzyme, particularly trypsin, reaching the unprotected mucous membrane of the left half of the colon. For that reason, therapeutic results might be obtained by vagotomy. However, one can completely paralyse the vagus nerve by atropine and accomplish the same end-result as is seen in vagotomised patients.

Furthermore, no-one knows at the present time what the section of the vagus nerve does to the gastro-intestinal tract. It is not an innocuous operation. That some individuals are no better after vagotomy for treatment of their peptic ulcer is evidence in itself that a complete vagotomy cannot be done in every patient. The fibres decussate into the œsophagus and the impulse is carried down into the myenteric plexus higher than the site of section of the nerves. I refer you to Waltman Walters's observations on this particular aspect of vagotomy in the treatment of peptic ulcer. Finally, ulcerative colitis is a disease of the parasympathetic nervous system. No-one to my knowledge has reported this manifestation occurring in Hirschsprung's disease.

One added thought regarding the innervation of the colon. If you do an ileostomy, hypermotility of the small intestine continues, but the right half of the colon is at rest. Therefore vagal fibres in themselves apparently do not innervate this portion of the bowel. If they did, you would not abolish hypermotility of the right half of the colon. There is no evidence, now, that there is a high titre of lysozyme secreted in the colon at the right half and in the ileum as the result of vagal stimulation.

With these facts in mind, I would have to state that there is no indication for vagotomy in the treatment of ulcerative colitis at this time. Maybe future clinical observations might make me change my mind.

Chicago. SIDNEY A. PORTIS.

CONTINUOUS DRIP TREATMENT OF PEPTIC ULCER

SIR,—Dr. Clark (March 11) has done a useful service by his careful evaluation of technique and theoretical considerations in the continuous drip treatment of peptic ulcer. However, his attitude to the management of this disease and the conclusions he draws ought not to remain uncriticised.

I doubt whether many will agree with him that this method is less trouble than more conventional Hurst or Sippy régimes. It is unlikely that it would often be practicable to maintain a patient's enthusiasm for this treatment for more than a few days at home, and even if this could be done it would be no substitute for the enforced rest, sedation, restriction of tobacco, and change of environment that treatment in hospital involves. It is this latter factor that is most important. The temporary removal of the social and psychogenic causes of his ulcer is surely of far greater importance than the drugs and milk preparations the patient takes.

Little can be concluded from the cases described. The figures are not well presented and the manner in which they are broken down is ambiguous. However, allowing for this, they are in no way remarkable and present no evidence that the drip method is an advance in treatment. No controls are produced to show the difference of response in another similar group treated more conventionally. Controls in this series ought to have been considered essential, for the cases are highly selected, in that all the patients are in receipt of a disability pension. Further comment on this is unnecessary, except to remark that the social and psychogenic factors in the production and maintenance of these patients' ulcers do not seem to have been considered.

The follow-up, which falls within the natural periodicity of the disease, does not show any improvement on the more conventional methods of treatment. The assessment of healing by radiological and clinical methods may well have missed several cases of ulcer which could have been demonstrated gastroscopically as being still active.

These criticisms are made chiefly to underline the extraordinary degree of empiricism which has ruled the management of peptic ulcer since the days this disease became a major social and industrial problem. From the great mass of writing and knowledge obtained concerning this disease, it is surely time the most rational and effective approach to this problem was abstracted.

Our empiricism, our varying standards of treatment, and our different opinions concerning ætiology and prevention, do not offer an effective challenge to this social menace. It is true to say that this argument applies to most diseases we attempt to treat, but a great advance would be made if the medical profession could be presented with authoritative and proven guidance on this particular problem.

Chelmsford. C. A. HOULDER.

A SUBJECTIVE VIEW OF ACUTE POLIOMYELITIS

SIR,—The excellent article on p. 460 of your issue of March 11 prompts me, having recently suffered a milder attack of poliomyelitis, to offer some reflections on the state of mind of the patient during the acute stage.

The standard textbooks describe the patient as "apprehensive": my own mental state was, by contrast, one of surprising indifference. Though obviously ill, I was quite unconcerned by my condition, and made no serious attempt at diagnosis! In spite of severe headache and cervical pain lasting for three days, I was not distressed and required neither sedative nor analgesic. Intense vertigo, which persisted, gradually diminishing, for several days, was the only symptom which occupied my mind at all frequently, and though the subjective sense of rotation was so gross as to defeat all my attempts to sit up, it alarmed me not at all.

This lack of insight continued, to a lesser degree, for a fortnight or more after the acute phase, and was associated with a highly exaggerated sense of well-being, and a totally unaccustomed tendency to bouts of facile laughter. This was certainly an alteration of emotional tone, and not an attempt, conscious or unconscious, at adjustment to the situation. The mental state, in fact, must have resembled that seen typically in the patient suffering from disseminated sclerosis, and did not revert completely to normal until the fifth or sixth week.

As an inexperienced student, I have had little opportunity of observing (adult) patients during the acute stage of poliomyelitis; but conversation with, and inquiry among, convalescent patients and others who have recovered lead me to wonder whether (particularly by comparison with the mood of patients in the general wards) the "couldn't care less" attitude and the subsequent euphoria might not be found to be almost as common as the classical apprehensive state. Even allowing for some toxic confusion, the comparative unconcern in retrospect not infrequently shown even by the severely paralysed patient in acute poliomyelitis is quite astonishing, and, I would add, extremely fortunate. Surely there cannot be so many stoics among us ?

L. W.

HOME HELPS FOR THE TUBERCULOUS

SIR,—I should like to draw attention to the following case. Application was made, in London, for a home help for a patient awaiting admission to hospital. This patient, though tuberculous, is not suffering from active tuberculosis, but from a complication resulting from a failed extrapleural *pneumothorax*. No help was forthcoming for a week—and then a very limited amount—although there was no-one to look after the invalid except another tuberculous person in full-time employment. When asked why help could not be supplied, the authority concerned explained that, out of 38 home helps, only 2 would attend the tuberculous, the rest being afraid of contracting this disease. A form had been issued to these workers which stated "I have been informed that there is a tuberculous patient at . . ." Probably such a form is used to safeguard the council against claims for compensation. I appreciate that it would not be possible to determine whether a worker had been infected through acting as a home help or through some everyday contact ; but is not the solution to recognise the possible risk, and pay danger money to those willing to work for all patients suffering from some infectious or contagious disease, and to include them in the categories covered by the Industrial Injuries Act ? Owing to the great shortage of hospital beds tuberculous patients cannot readily gain admission, but on the other hand, unless they are very fortunate, they cannot have the services of a home help.

London, S.W.6. E. D. ANDREWS.

*** We comment on Miss Andrews's letter in an *annotation* this week.—ED.L.

POTASSIUM DEFICIENCY IN *p*-AMINOSALICYLIC ACID THERAPY

SIR,—In bringing to light the question of serum-potassium levels in P.A.S. therapy, Dr. Cayley (March 11) has done a service to those working on the chemotherapy of tuberculosis ; but I wonder whether the title of his paper should not have been "Potassium Deficiency in Prolonged Sodium Salt Administration," rather than imply that a depression of the blood-potassium level is associated with the *p*-aminosalicylic radicle.

In this connection it would be interesting to hear whether, in fact, it was the sodium salt of *p*-aminosalicylic acid that was used on the three cases which he cites. As you know, Sir, it is sodium P.A.S. which is predominantly used in this country in the treatment of pulmonary tuberculosis, and—whereas free acid granules and other salts are available—it is not unreasonable to suppose that the administration of a sodium salt over periods of ten weeks, five weeks, and four weeks (as in the 3 cases) in fairly high dosage might well so alter the sodium-potassium ratio as to cause depression of the serum-potassium level.

I am sure that it will be agreed that Dr. Cayley has not shown that "in patients with pulmonary tuberculosis under *treatment with* . . . P.A.S. the serum potassium may be dangerously lowered," since :

(1) this may be a "sodium effect" as suggested ;

(2) only 2 cases are described with a reduced serum-potassium level ; and

(3) in case 2, the reduction is not of a "dangerously low" order.

In the Scandinavian countries where free P.A.S. (as opposed to its sodium salt) has been in use for some six years now, no effect on potassium metabolism has been reported.

These criticisms are in no way intended to minimise the value of Dr. Cayley's findings, which are of some importance in view of the present-day trend towards prolonged administration of sodium *p*-aminosalicylate ; but I would point out that this depression of serum-potassium level is one of the factors which has prompted the clinical trial, at present proceeding, of calcium *p*-aminosalicylate, the initial results with which seem promising.

Grove Park Hospital, London, S.E.12. M. M. NAGLEY.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

SIR,—I read with great interest the articles by Mr. Ewing and Dr. Kiloh in your issue of Jan. 21. In the subsequent correspondence on the prevention of such lesions I have been rather surprised to find no reference to the simple apparatus illustrated here. This, I believe, was designed in the Western Infirmary, Glasgow.

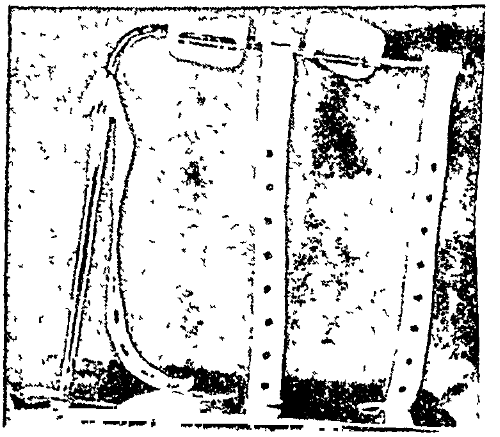

Fig. 1—The vicson arm-rest.

For abdominal surgery both upper limbs are placed in the slings, where they are out of the way of the surgical team and readily available to the anæsthetist. For operations on the breast or axilla, the forearm on the affected side is padded with cotton-wool and carefully

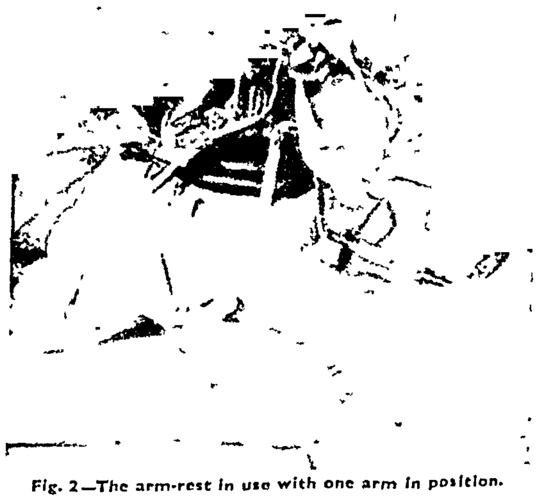

Fig. 2—The arm-rest in use with one arm in position.

bandaged to the vertical part of the bar. The angle of the arm can be adjusted to give the optimum exposure, traction on the plexus being minimised by the flexion and pronation of the forearm.

For intravenous injections with this apparatus the cephalic or radial veins are used. The veins on the dorsum of the hand are of course readily available, but the use of a needle with Gordh diaphragm adaptor in a cephalic vein avoids multiple punctures. The cephalic and radial veins are more suitable than the median basilic or median cephalic for infusions of blood or plasma.

The use of this or some similar support would appear to have some place in the prevention of lesions of the brachial plexus.

The 'Vicson' arm-rest is manufactured by Messrs. Vicarey, Davidson & Co., 162, Bath Street, Glasgow.

Royal Naval Hospital, Plymouth. A. D. SINCLAIR.

SOCIAL SIGNIFICANCE OF SYMPTOMS

SIR,—In his article of Feb. 11 Dr. Gooddy has done good service in bringing to light the manner in which the unrecognised neurotics are clogging the working of National Health Service and greatly adding to its cost by their repeated demands for medical attention, recognition of their symptoms, and special examinations. However, he seems to have failed to appreciate that in psychopathology the symptom is a very complex structure, that its roots extend deep into the personality, and that it is in many respects an anachronism. It plays an important part, for it strives to serve a dual purpose—that of attaining some measure of solution or expression of a deep unconscious conflict, or the partial gratification of an equally deep and unknown want, while at the same time it is used as a defence against the anxiety which may arise from the "wish" for gratification of primitive instinctual urges.

Often when listening to the neurotic's tale of woe I am reminded of the lines of Richard Lovelace (1618–58) which he wrote to Althea from prison :

> " Stone walls do not a prison make
> Nor iron bars a cage;
> Minds innocent and quiet take
> That for an hermitage ;
> If I have freedom in my love
> And in my soul am free ;
> Angels alone, that soar above,
> Enjoy such liberty "

I read these lines as a boy in my grammar book, but they were then rendered noxious to me by the addition of a single sentence—"Parse and analyse the above lines." Now isn't that in a sense exactly what happens when the neurotic is relating his symptoms ?—we make a critical analysis of his words instead of trying to understand the full meaning for him of the symptoms which he describes so vividly and often with so much emotion. If we listen attentively we shall appreciate that he is in a state of conflict ; he is a prisoner and yet his own gaoler ; he is yearning for that "something" which is portrayed in the above lines ; he feels frustrated because he cannot get understanding or help as to how to achieve his objective. "Broken glass in the stomach" is a very graphic way of describing a feeling of "pent up jangled emotions inside one," or again the act of smoking beneath a "No Smoking" notice is evidence of a deep rebellion against the world which doesn't attempt to understand and thwarts him at every turn.

I appreciate that it takes time, patience, and experience to listen to these people and unravel their difficulties, to lay bare their deeper wants and conflicts, and show them some real road by means of which they may at least try to reach the desired goal.

Undoubtedly several factors may be exacerbating the prevalence of neurosis today. The National Health Service Act has promised free treatment—whether of the body or psyche—and at the same time we have an elaboration of the social services and assurances of freedom from want ; so no wonder the neurotics, with their "unknown wants" come flocking for treatment and will not be easily put off. They will tend to produce new symptom complexes until they get what they want or give up in despair. Present trends in mechanised production are another factor, for many neurotics, who can adapt happily to a certain tempo, are unable to keep pace when this is increased. And in mass production the worker is often employed on uninteresting repetitive processes, instead of having the satisfaction of seeing "his job" finished.

Bishop's Stortford, Herts. D. N. HARDCASTLE.

AGAROL

SIR,—The Minister of Health mentioned 'Agarol' in the House of Commons on March 14, and asserted that it was "the subject of heavy advertising." Neither agarol compound nor any other William R. Warner product has ever been advertised to the public in this or any other country. Their sale results entirely from medical prescriptions and recommendations.

The Minister's comparisons were somewhat misleading :

1. The price difference between the prescription pack of agarol and the substitute emulsion is not as great as indicated ; and we understand that, with the N.H.S. system of averaging scripts under 5*s*., the 14 oz. agarol costs the Exchequer exactly the same as the *N.F.* substitute—usually between 2*s*. and 3*s*. If agarol happens to be in the list from which the average is computed, it will put the average up a trifle more than does the substitute.
2. Although the *N.F.* formula is offered as a substitute for agarol, it is not identical.
3. Agarol is manufactured to a standard of quality by a process which is not used by most, if any, manufacturers of the *N.F.* substitute.
4. The whole cost of evolution of the agarol formula and of its introduction to the medical profession was borne by this company.

VITAMIN B_{12} AND PERNICIOUS ANÆMIA

SIR,—Certain references to my work in your leading article last week require qualification.

> ". . . small doses, such as 10 µg., produced a reticulocytosis but no satisfactory subsequent rise in red cells or hæmoglobin."

The fact is that 10 µg. produced a mean rise of red blood-cells in 15 days about equal to the "average" standard of Della Vida and Dyke (1942) for response to liver extract. Such responses would normally be regarded as "satisfactory," but we found that larger doses produced even greater effects, roughly in proportion to the logarithm of the dose.[1] Fortnightly doses of 10 µg. of vitamin B_{12} were tried experimentally under closely controlled conditions, and found not to be adequate for all cases. For routine purposes in patients whose blood is examined only once in 6 months we usually give 30–60 µg. every three weeks. Reasons for giving larger doses to patients with subacute combined degeneration are discussed elsewhere.[2]

The preceding remarks refer to vitamin B_{12} itself. With respect to varieties of vitamin B_{12} derived by Lester Smith from *Streptomyces griseus*, sufficient time has not yet elapsed for a satisfactory determination of requirements either for maintenance or for patients with subacute combined degeneration.

The following sentence should be modified by inserting the words which I have put in italics :

> ". . . considers that a mixture of 5 µg. of vitamin B_{12} with 50 ml. of human gastric juice *given daily* has about the same hæmopoietic effect as a *single dose of* 10 µg. of vitamin B_{12} given parenterally."

---

1. Ungley, C. C. *Brit. med. J.* 1949, ii, 1370.
2. Ungley, C. C. *Brain*, 1949, 72, 382.

Incidentally this applies to only 1 of the 3 cases which I reported at the meeting of the Royal Society of Medicine to which you refer; the ratio between the total dosage of vitamin B_{12} given orally with gastric juice and the dose which would probably be needed by injection to produce an equivalent response varies considerably from case to case.

The Royal Victoria Infirmary,
Newcastle upon Tyne.
C. C. UNGLEY.

SIR,—In view of last week's report by Dr. Dyke and his colleagues on the synthesis of vitamin B_{12} in the alimentary tract of a man at autopsy, it may be of interest to refer to work carried out at the University of Michigan in 1948 and 1949 during the tenure of a Rockefeller fellowship, and reported to the Scottish Society for Experimental Medicine in October, 1949. This was the preliminary part of an investigation of the extent to which remissions and relapses in patients with megaloblastic anæmia might be related to the production or destruction of pteroylglutamic acid or vitamin B_{12} by bacteria in the small intestine.

An intestinal tube was passed to the lower end of the ileum in three patients with pernicious anæmia in relapse and two controls. All these patients were fasting. The secretions of the alimentary tract were assayed for pteroylglutamic acid, and for growth factors for *Lactobacillus leichmanii* (chiefly vitamin B_{12}). In none of the subjects was there any significant amount of vitamin B_{12} or pteroylglutamic acid in the small intestine. In patients and controls the contents in a day's stools were about 5 µg. of vitamin B_{12} and 0·5 mg. of pteroylglutamic acid. In a patient with ulcerative colitis, each ml. of material obtained from the lower end of the ileum contained approximately 0·03 µg. of growth factors for *L. leichmannii* and 12 µg. of pteroylglutamic acid—much larger amounts than in the other patients, but not surprising in view of the fæcal nature of the aspirated material.

It was considered unlikely that relapses and remissions in pernicious anæmia could be associated with changes in the intestine flora of the small intestine. Further experiments are in progress.

Department of Medicine,
University of Edinburgh.
R. H. GIRDWOOD.

SIR,—In your leading article last week you state: "There is now sufficient evidence for us to say that preparations of vitamin B_{12} from liver or from *Streptomyces griseus* will produce a remission in pernicious anæmia, and that regular dosage will maintain a normal blood picture."

Some of your readers may hold less categorical views as a result of their own experiences. There is of course evidence to indicate that vitamin-B_{12} preparations *may* produce remission in pernicious anæmia and that they may also be able to maintain a normal blood picture; but judging from reports reaching us of the inability of vitamin-B_{12} preparations alone to do so in many cases, some qualification of your conclusion appears to be required.

ALMROTH WRIGHT AND UNDULANT FEVER

SIR,—May I add one item to the rich harvest of knowledge about undulant fever which Sir Weldom Dalrymple-Champneys has given us in his Milroy lectures, published in your last two issues? Almroth Wright was, I think, the first to attempt prophylactic immunisation of man against this disease.

A few experiments with monkeys had shown that some degree of protection was afforded by inoculation with either a dead or living culture of *Brucella melitensis*, but no more animals were available. Wright backed his belief that immunisation would be effective (this was before the days of anti-typhoid inoculation) by injecting himself with a killed vaccine and afterwards with a living culture. Unfortunately the protectio if any, was not adequate, and he went down with very unpleasant attack of Malta fever which laste many weeks. He often told me of *the misery of tho* weeks, with their drenching sweats.

Was this, perhaps, the earliest instance of an attemp at preventive inoculation with a killed vaccine and "challenging dose" of living culture?

EPIDEMIC MYOSITIS ON BOARD SHIP

SIR,—In view of the comparative rarity of epidemi myositis (*Diaphragmatic pleurisy*) the following smal outbreak in a passenger liner seems worth recording I have not been able to trace a previous epidemic in passenger ship, but Huss[1] described one in two Swedis warships that called at Marstrand. The crews wer healthy on arrival, but epidemic myositis was presen in the village. A few days after the ships had sailed som cases were seen in both ships, and within a month 34% of the men were affected.

In the present instance the passenger liner carried 2140 persons—1530 passengers, and 610 crew. Altogether 34 persons were affected—1 officer, 19 passengers, and 14 crew. All these cases had their onset within 19 days. These are conservative figures, for several cases of stiff neck, painful neck, shoulder, and arm, and 3 cases of pain in the chest, all among the crew, and 3 or 4 cases of unexplained abdominal pain and pyrexia in children probably also belong to the series; but these have been excluded because their probable ætiology was not recognised at the time. All the cases were in adults aged 17–30, except 2 in children aged 5 years and 7 years and 1 in a female passenger aged 37.

As in all previously reported outbreaks of epidemic myositis, these cases occurred during hot weather. The symptoms lasted 2–4 days, with two exceptions, one of 19 and one of 64 days (with a remission of 30 days in the middle of this period).

The outstanding symptom was pain, usually over the right costal margin but sometimes on both costal margins and less frequently on the left side only. In most of the cases either the patient complained of pain in the right hypochondrium or pain could be elicited by pressure. The woman of 37 had pain over the gall-bladder area for 11 days before there was any chest pain, and this case was at first mistaken for cholecystitis. The pain was worse on deep breathing, movement, or pressure. Recurrences of pain were common in this series. The pain was never very severe and could not be compared with the "devil's grip" reported by American workers.

There was seldom any pyrexia. The patient whose condition was at first mistaken for cholecystitis ran a temperature of 101–102°F for six days, and the two children had temperatures of 101° and 101·6°F. In the longest illness (64 days) pyrexia lasted only seven days. Nichamin[2] states that more than half his 75 cases were practically apyrexial, and McDaniel[3] says that almost all his cases were without fever, whereas Macdonald[4] reports fever in 91% of 70 cases, and Jamieson and Prinsley[5] report that 34 of 35 cases were pyrexial from the onset.

Dizziness, headache, and weakness were common. No vomiting or disturbance of the bowels was noticed among the adults.

No pleural rub was heard in any case, but this may have been due to the difficulty of auscultation on board

---

4. Macdonald, R. R. *Penn. med. J.* 1938, 41, 919.
5. Jamieson, W. M., Prinsley, D. M. *Brit. med. J.* 1947, ii, 47.

ship. Williamson[6] heard a pleural rub in 7 of 13 cases, and Attlee et al.[7] in 17 of 48, whereas Fulghum[8] heard none in 28 cases, and most of the American observers have not heard one.

The importance of epidemic myositis is twofold: (1) it is very distressing to the patient, and a correct diagnosis will relieve the anxiety of both patient and physician; and (2) it often mimics serious abdominal disease[9] and has led to unnecessary abdominal operations.

WAR

SIR,—Dr. Comfort has widened my thesis in an able and stimulating letter. War is a great destroying river to which many sources contribute. Much can be written about the part played by government—fanatical, corrupt, or complacent and indolent—by psychopaths in office and out of it, by social pressure and economic necessity and their psychological effects. In these articles I was concerned to emphasise and inquire into that vital contribution to war which does come from the minds of ordinary men. In my opinion too few of us have accustomed ourselves to looking into the glass and saying: "There goes a war-monger." It isn't easy to do!

It is very necessary to attach full weight to the peculiar horrors and madnesses of war, such as the pogroms and the bombings and their origins and release in the minds of clever men who lead us. But I am even more worried about the way the ordinary mind can be innocently fanned towards war (hot or cold) by leaders who, in a more healthy world, would have to relegate their energies to brisk journalistic invective.

In any study of periods of pre-war history I would pick out as a common factor the growing conviction on both sides that it is impossible to deal with the opposite side other than by force. Just before war breaks out this view seems to become so widespread as to be all but universal. I am fairly sure that this is in essence just that basic attitude to an enemy which has made the introduction of law a pragmatic necessity. Therefore, it is World Law that we now need.

As for government crimes, these are committed just in the very sphere in which the government has ceased to be the lawgiver to its people and has become the lawless and independent "sovereign State" for whose enchainment the ordinary man now awaits. I agree with Dr. Comfort that in this function governments are the enemies of mankind. Indeed it becomes reasonable to ask for a bloodless revolution against the "sovereign State" as such. But today evidence accumulates that some leading statesmen and publicists can see this dual rôle of the nation State—lawgiver at home, naughty-boy abroad—rather more clearly than can most ordinary men! When we belabour the psychopath in office do not let us forget that wisdom, courage, and idealism sometimes get into high places too.

We therefore ask national governments, as Hobbes once asked individuals, to "confer all their power and strength upon One Assembly" to "get themselves out of that miserable condition of Warre" which is consequent upon "the naturall Passions of men when there is no visible Power to keep them in awe." I for one do not see why governments and parliaments willing to abnegate their sovereignty should not be found sufficient in numbers and power to the task in hand—namely our collective peace and continuance.

Edinburgh.

RANYARD WEST.

PERSONALITY AND NURSING

SIR,—All the objections which Dr. Hamilton raises in his letter of March 11 are considered and discussed in the detailed statistical report of the investigation which is to be published in the *Journal of Consulting Psychology*. As *The Lancet* did not feel that such a statistical report would be of interest to any but very specialised readers, these points were not discussed in the article published, on Feb. 25, in this journal.

It is almost certain that these considerations would reduce the size of the multiple correlation to some slight extent. Both Vernon[1] and Wagner,[2] however, report results in related fields which would lead to a very small reduction, if any, in the size of the correlation. Moreover, the reduction of the multiple correlation is not such a simple phenomenon as readers of the letter might be led to believe. It is frequently reduced, especially when the selection of tests is based on no theoretical rationale; but there are many cases, particularly that of the American Army Aviation Project, where no such reduction was observed. The results of using tests on all applicants, for which facilities are now provided, will answer some of the other questions raised.

It is difficult to discuss these rather complex statistical points in an article of this type. We hope that they have been fully covered in the detailed statistical report.

EPIDEMIOLOGY OF POLIOMYELITIS

SIR,—During the epidemic of poliomyelitis in 1947, a few articles appeared in the medical press suggesting that fæcal pollution of the permanent way spread the disease. It was pointed out, however, that railway tracks were also a mode of communication between human beings, and consequently the idea of fæcal pollution rather than carriers was more or less ruled out. I suggest, however, that this mode of spread should be carefully reconsidered.

Reports on the epidemiology of poliomyelitis provide evidence that flies can carry the virus, and it appears that in our future efforts to prevent the spread of infection strong efforts should be made to secure the coöperation of the public in protecting foodstuffs, fruit, vegetables, and liquids from contamination by flies.

As is well known, American investigators (Paul and Trask) have demonstrated that the virus can be recovered with ease from the stools of patients with the paralytic and with the common abortive types of the disease. One convalescent harboured the virus in his intestinal tract for 125 days. The same investigators succeeded in isolating the virus from the sewage of urban communities in which poliomyelitis was epidemic; nineteen specimens collected from sewers in the vicinity of isolation hospitals in which cases of poliomyelitis were being treated, yielded the virus.

At a meeting of the Royal Society of Medicine in October, 1943, Dr. Robert Cruickshank stated: "The possibility of flies acting as vectors of the virus should be considered in view of the fact that American work had shown that the virus can be recovered from blow flies and green bottle flies with access to the fæces of acute and convalescent cases of poliomyelitis." Prof. H. J. Seddon remarked that in the war-time Malta epidemic flies were unduly prevalent; in the devastated areas there were quantities of garbage that could not be cleared away, as well as the sewage that was used for fertilising crops.

In these articles I was concerned to emphasise and inquire into that vital contribution to war which does come from the minds of ordinary men. In my opinion too few of us have accustomed ourselves to looking into the glass and saying: "There goes a war-monger." It isn't easy to do!

It is very necessary to attach full weight to the peculiar horrors and madnesses of war, such as the pogroms and the bombings and their origins and release in the minds of clever men who lead us. But I am even more worried about the way the ordinary mind can be innocently fanned towards war (hot or cold) by leaders who, in a more healthy world, would have to relegate their energies to brisk journalistic invective.

In any study of periods of pre-war history I would pick out as a common factor the growing conviction on both sides that it is impossible to deal with the opposite side other than by force. Just before war breaks out this view seems to become so widespread as to be all but universal. I am fairly sure that this is in essence just that basic attitude to an enemy which has made the introduction of law a pragmatic necessity. Therefore, it is World Law that we now need.

As for government crimes, these are committed just in the very sphere in which the government has ceased to be the lawgiver to its people and has become the lawless and independent "sovereign State" for whose enchainment the ordinary man now awaits. I agree with Dr. Comfort that in this function governments are the enemies of mankind. Indeed it becomes reasonable to ask for a bloodless revolution against the "sovereign State" as such. But today evidence accumulates that some leading statesmen and publicists can see this dual rôle of the nation State—lawgiver at home, naughty-boy abroad—rather more clearly than can most ordinary men! When we belabour the psychopath in office do not let us forget that wisdom, courage, and idealism sometimes get into high places too.

We therefore ask national governments, as Hobbes once asked individuals, to "confer all their power and strength upon One Assembly" to "get themselves out of that miserable condition of Warre" which is consequent upon "the naturall Passions of men when there is no visible Power to keep them in awe." I for one do not see why governments and parliaments willing to abnegate their sovereignty should not be found sufficient in numbers and power to the task in hand—namely our collective peace and continuance.

PERSONALITY AND NURSING

SIR,—All the objections which Dr. Hamilton raises in his letter of March 11 are considered and discussed in the detailed statistical report of the investigation which is to be published in the *Journal of Consulting Psychology*. As *The Lancet* did not feel that such a statistical report would be of interest to any but very specialised readers, these points were not discussed in the article published on Feb. 25, in this journal.

It is almost certain that these considerations would reduce the size of the multiple correlation to some slight extent. Both Vernon[1] and Wagner,[2] however, report results in related fields which would lead to a very small reduction, if any, in the size of the correlation. Moreover, the reduction of the multiple correlation is not such a simple phenomenon as readers of the letter might be led to believe. It is frequently reduced, especially when the selection of tests is based on no theoretical rationale; but there are many cases, particularly that of the American Army Aviation Project, where no such reduction was observed. The results of using tests on all applicants, for which facilities are now provided, will answer some of the other questions raised.

It is difficult to discuss these rather complex statistical points in an article of this type. We hope that they have been fully covered in the detailed statistical report.

EPIDEMIOLOGY OF POLIOMYELITIS

SIR,—During the epidemic of poliomyelitis in 1947, a few articles appeared in the medical press suggesting that fæcal pollution of the permanent way spread the disease. It was pointed out, however, that railway tracks were also a mode of communication between human beings, and consequently the idea of fæcal pollution rather than carriers was more or less ruled out. I suggest, however, that this mode of spread should be carefully reconsidered.

Reports on the epidemiology of poliomyelitis provide evidence that flies can carry the virus, and it appears that in our future efforts to prevent the spread of infection strong efforts should be made to secure the coöperation of the public in protecting foodstuffs, fruit, vegetables, and liquids from contamination by flies.

As is well known, American investigators (Paul and Trask) have demonstrated that the virus can be recovered with ease from the stools of patients with the paralytic and with the common abortive types of the disease. One convalescent harboured the virus in his intestinal tract for 125 days. The same investigators succeeded in isolating the virus from the sewage of urban communities in which poliomyelitis was epidemic; nineteen specimens collected from sewers in the vicinity of isolation hospitals in which cases of poliomyelitis were being treated, yielded the virus.

At a meeting of the Royal Society of Medicine in October, 1943, Dr. Robert Cruickshank stated: "The possibility of flies acting as vectors of the virus should be considered in view of the fact that American work had shown that the virus can be recovered from blow flies and green bottle flies with access to the fæces of acute and convalescent cases of poliomyelitis." Prof. H. J. Seddon remarked that in the war-time Malta epidemic flies were unduly prevalent; in the devastated areas there were quantities of garbage that could not be cleared away, as well as the sewage that was used for fertilising crops.

[2] Wagner, R. *Personnel Psychology*, 1949, 2, no. 1.

Kessel et al.[1] were able to isolate the virus from the stools and colon contents of patients and at autopsies within three weeks of the onset. Of 35 patients under 15 years of age, 40% yielded the virus; 22% of stools from patients with paralysis and 19% of stools from patients without paralysis yielded virus.

Horstmann[2] writes:

> "The sudden burst of cases with the appearance of warm weather repeats itself again and again, and if summer comes early, so do epidemics. The first large epidemic in England in 1947 came in with unusually long and warm weather. Why does not the virus spread in winter as do other contact diseases? The virus is present in winter. Virus has been isolated from flies trapped during epidemics of poliomyelitis and from flies caught in clean surroundings where sanitary conditions have been excellent. . . . both flies and poliomyelitis flourish in summer; they may be an important link in the chain leading to poliomyelitis epidemics."

Francis et al.[3] proved that the virus from fæces of patients with poliomyelitis was actually taken up by flies and recovered by inoculation of rhesus monkeys. Kessel and his colleagues[1] isolated the virus from the stools of 20% of patients, but not once from 139 nasal washings. The virus has also been recovered from non-biting flies in the neighbourhood of infected persons.[4]

Thus the evidence indicates that the virus is probably present in the fæces of a large number of patients and abortive cases. To dispose of fæces in a primitive fashion along the permanent way is surely to court danger, especially during hot summer weather when flies are prevalent.

From the aspect of prevention I would emphasise the importance of measures to eradicate flies and remove their breeding-places. I would suggest that all public libraries should affix a small slip on the inside cover of each book, bearing the slogan in red capitals: "keep polio at bay—kill that fly." Other measures would include thorough washing of all fruit and vegetables before being eaten. The many excellent posters dealing with the anti-fly campaign issued by the Central Council for Health Education should also be prominently exhibited.

I am aware that I have covered old ground in this letter, but I feel that the obvious measures should not be neglected.

PNEUMOCONIOSIS AFTER EXPOSURE TO SULPHUR DIOXIDE FUMES AND DUST FROM COKE FIRES

SIR,—First, may I remind Dr. Fisher that our paper of Dec. 31 described our conclusion as tentative? Secondly, I would suggest that he has misapprehended the problem we dealt with: otherwise he would not speak, as in his letter of March 11, of pneumoconiosis caused by coke ash. The report concerned lesions appearing after exposure to both SO_2 fumes and dust from coke fires. Thirdly, I should like to add two other facts in favour of our findings: (*a*) Professor Pancheri (Milan) has found (see *Lancet*, Feb. 4, p. 226) that "in the sulphur industry workers are exposed to both dusts and fumes with ensuing dyspnœa, cyanosis, bronchitis, emphysema, and even bronchiectasis." (*b*) The case of a stoker was recently brought to my notice by his own doctor after perusal of our paper. This man's chest film showed definite pneumoconiosis.

Parliament

Health Service Costs

CHANCELLOR'S PROMISE OF LIMITATION

IN the House of Commons on March 14, replying to the Opposition's amendment which deplored the failure of the Chancellor of the Exchequer to enforce his own instructions to departments not to overspend extensively their estimates for the current year, Sir STAFFORD CRIPPS admitted that the supplementary estimate for the National Health Service was larger than all the others put together. But he justified the extra £98 million asked for on the ground that this was a very special case. The largest item, that for hospitals and specialists, was to supplement estimates which had been submitted by hospital management committees in August, 1948, when they had only recently been appointed and some had only skeleton staffs. Sufficient time had not elapsed for an adequate review of the hospitals, and in many cases no satisfactory accounts existed on which firm estimates could be based. With a view to making economies, or at least avoiding extravagances, the estimates were reduced by £12 million in the main estimates. But unfortunately it turned out that the management committees and regional boards had underestimated rather than overestimated their expenditure, and it became clear that the estimates could not be brought within the lower sum without closing hospital beds, which the Government were not prepared to do. The revised estimate produced on this basis gave rise to the increase of £50 million on the item hospital and specialist services. Some provision for the implementation of the Spens report on specialists had been made, but the sum to be paid in the current year exceeded this by £10 million. A further £7 million was needed to meet Whitley awards to nursing and other staff. The balance—about £20 million—was due partly to lack of material on which to make estimates and partly to increased prices.

The other three items of importance, Sir Stafford continued—pharmaceutical, dental, and supplementary ophthalmic services—showed between them an excess of about £45 million. Though there was an element in this of price change, by far the greatest factor was consumer demand, which had lasted much longer and at a much higher level than was expected. These were the special circumstances of the launching of this vast new service, and when these new factors were first encountered in the early summer of last year there were only two ways of dealing with the matter—either to shut down the beds and discontinue other services so as to keep within the estimates, or to maintain the services with the greatest possible economy. The Government unhesitatingly took the second alternative. He was quite sure that the Opposition leaders would have done the same thing. It would have been unthinkable for any responsible Government suddenly to discontinue these essential health services on the ground that a supplementary estimate was undesirable.

But everyone recognised that there was a limit to the speed of the development of the service, and he himself believed that it was now necessary to call a halt. The estimates for the forthcoming year must be regarded as a ceiling. Also, since such a large annual sum of money was at stake in the hospital services—about two-thirds of the total vote—some means must be found to associate the Ministry of Health more directly with the management committees and the regional boards to ensure that budgets were not exceeded once they were passed or savings on one subhead unnecessarily dissipated on another. How best this association could be achieved would be settled after the Minister had consulted the regional hospital boards and the management committees.

The Government would not be satisfied until the new service had been thoroughly examined in all its incidence, and so knitted together in its organisation as to ensure that there was no waste or extravagance. They wanted to provide the best health service the nation could afford, and a first-class service was not something which could be got on the cheap, but expenditure on health must be

brought into proper proportion with food subsidies, education, and other vital matters.

Mr. F. Messer held that the implication of the Opposition's amendment was that the Minister should have restricted the service, but those facing great tragedy because of disease could not listen with equanimity even to what the Chancellor had said. There was need for a great deal more to be done, especially in the tuberculosis services. No fewer than 10,000 people were waiting to get into sanatoria. He would like to persuade Parliament to spend even more money on the health services. Another grave matter was that since the introduction of the service there was greater difficulty in getting accommodation for old people in hospitals. The hospitals had been up-graded, but the tendency was to use them for acute cases, which meant less accommodation for chronic cases. Hospitals were unfitted to be dealt with under the Treasury system of finance which did not allow them to carry an unexpended balance from one year into the next. Thus hospitals had no incentive to make effective economies, and Treasury finance could prove an inducement to wasteful spending.

In his maiden speech, Dr. Charles Hill affirmed that whatever controversies had raged in the past as to the form the health service should take, the people of the country were now anxious that it should be a resounding success. The Minister's difficulty was to reconcile local budget preparing at the hospital management committee level with central financial control, and Dr. Hill welcomed the Minister's decision in future to make allocations of money, not earmarked for particular hospital management committee, to regional hospital boards for allocation. Even so, with all possible central economies effected, it was impossible not to expect a substantial increase in hospital expenditure when it was remembered that the proportion of expenditure for capital development was only 5%. Looking at the problem in isolation he could see the prospect of increased expenditure—justifiable in relation to hospital considerations—of £100 million or even £200 million in the next few years. But if there was a limit to what could properly be raised and if such expenditure was a reasonable possibility, then we faced the crucial issue of the priority of social services in relation to limited resources. We must choose between hospitals and houses, between clinics and schools.

The one way of strengthening the hand of the Minister of Health was the predetermination of the money available for the health service. In the hospital service this would mean an annual allocation of money to regional hospital boards, and in turn to hospital management committees. It might have the further advantage that the public, recognising the limit to which the Chancellor referred, would return once more to their old and friendly supporting attitude towards the hospitals.

The principle of allocation already existed within limits in the general-practitioner field, and was one of the reasons for the more modest supplementary estimate that field. If the allocation principle was applied to the dental service it would be possible to give expression at last to the Government's policy of priority—the dental care of mothers and children.

The increase in the cost of the pharmaceutical services, Dr. Hill pointed out, was only due in part to an increase in the number of items of service. It was also due to the cost of the newer drugs, but they contributed to the service elsewhere by shortening periods of illness. He admitted that one cause of the increased cost was the pressure of the middle-classes for the proprietary medicines to which they were accustomed. But he hoped that the tendency to regard a large number of the lesser items demanded of the service, and of the doctors in particular, as frivolous would cease. The whole object was to bring to the doctor the trivial to prevent it becoming a tragedy.

Dr. Barnett Stross found himself in agreement with all that Dr. Hill had said, including his gentle regret at the terms meted out to the general practitioner, who bore the brunt of the service. It was fascinating to know that his average salary was £1530 a year, while his prescriptions cost £1700 a year. On the whole Dr. Stross thought the dentists had done a good job, but why could not the Minister make it a condition of service for the dentist to take a percentage of children?

Mr. Iain MacLeod found it indefensible that the dentists should be paid so much more than the doctors. Relative to their training, qualifications, ability, the responsibility that they ceaselessly shouldered, and the hours they worked, doctors were by far the worst paid profession in the service. It would be unwise to presume too far on their infinite and most statesmanlike patience.

Dr. H. B. Morgan said the health service was a personal treatment scheme, and it was different from preventive medicine, social medicine, and industrial medicine. It was available to all on free and equal terms and therefore he disliked the system of priorities. He knew they were essential today for certain classes, such as mothers and children, but he wanted to see the day when there was no shortage of doctors or dentists, and no question of hospital accommodation not being available. He deprecated the introduction of parsimony into the question of the cost of the National Health Service.

Mr. Somerville Hastings said that in so far as the cost of the health service was new expenditure, that was surely an indictment of what had been done for the health of the nation in the past. What had been done was to transfer to a large extent individual expense and make it collective. Because of the value of our man-power, and the need to increase production, the country must spend on health all that was necessary, provided that it was done with care and economy. The fact that so much more could now be done for the welfare of patients and so many more recoveries were recorded, made expenditure on health today more worth while than it had ever been. He suggested that more should be done to keep hospital beds in constant occupation, for a staffed bed cost little more occupied than empty. Could not more use be made of the fever hospitals for convalescent cases? A bed bureau for a whole group of hospitals was essential and one doctor should have the duty of seeing that no beds were empty. If more full-time specialists were employed in hospitals there would be less travelling time to pay for. Some specialists at present were working in as many as 13 hospitals.

Mr. Aneurin Bevan, Minister of Health, caused some laughter by congratulating Dr. Hill on a maiden speech with which he was largely in agreement. The real point of the debate, he declared, was whether the Chancellor of the Exchequer and the Government were right in permitting the expansion of the health service to go on during the last year. We had to wait at least one year to see what the behaviour pattern of the people would be in respect of spectacles, dentistry, drugs, or doctors before it was possible to form the least estimate of what the expenditure would be. When hospital authorities were accused of maladministration members of all political parties who were serving on the management committees and regional boards were being indicted. He did not say there ought not to be a tightening of hospital administration; and there would be. There must be a closer identification of the central government with the local units of hospital administration. We had inherited a hospital system with no system of accountancy. Comparing costs in other countries he said that since 1946 hospital costs in the United States of America had gone up 40% and in Sweden 50%. The Royal Masonic Hospital and the King Edward VII Sanatorium were both outside the scheme, and their costs had risen 55·8% and 69·4%. In the N.H.S. costs rose by 40%.

But he agreed that economies ought to be made, and he believed savings could be made quickly in the cost of proprietary medicines, which had become part of the racket of civilised society. Take one preparation, 'Agarol' emulsion, six ounces of which cost 3s., on the N.H.S. list cost 10½d.; 'Genasprin,' 1s. 9½d., on the N.H.S. list 2½d.; 'Dexedrine' tablets 3s. 2d., on the N.H.S. list 9½d. All these preparations were widely advertised, and many doctors prescribed them. He hoped to get the coöperation of the profession, Parliament, and the public to cut out proprietary medicines which were unnecessarily expensive. They had had to get hospital glassware from Germany to break the monopoly in Great Britain. A large sum of money had been saved in this way, even after paying import duty. On X-ray apparatus, by cutting out the retailer, £150,000 a year had already been saved, and on X-ray films £280,000 a year. On hearing-aids and batteries they had saved £$1^1/_2$ million, and on streptomycin £240,000. In all, by cutting out retailers' costs they had saved over £$2^1/_2$ million, and as the N.H.S. and the supply organisation established themselves, many savings would be made in various directions. The Opposition amendment was not only an attack on the Government but a concealed and cowardly attack upon the N.H.S. by people who had not the honesty to make it openly. The amendment was negatived by 308 votes to 289.

Therapeutic Social Clubs

On the motion for the adjournment in the House of Commons on March 17, Mr. J. W. SNOW sought the Minister of Health's encouragement for the promotion of more therapeutic social clubs. Briefly reviewing their history he explained that shortly before the war a small group of psychiatrists decided that purely institutional treatment was not a complete answer for mental illness. They thought it might be beneficial if they could provide a method of social intercourse such as a club, which would impose self-responsibility upon mental patients. This was the origin of the so-called inpatient club. Mental treatment in this country, Mr. Snow suggested, had passed through three periods: the primitive period, the more enlightened scientific or philanthropic period, and the present participatory period. Thus these clubs were organised by the patients themselves who became partners in the operation of treatment. Then the psychiatrists who had started the inpatient club thought an outpatient club might be something better. Now there were a number of these clubs operating outside the hospitals. In London the L.C.C. had given valuable help and he hoped the idea would spread to Scotland, Wales, and the provinces. The underlying principles of the clubs were prevention and cure. By their membership many patients avoided inpatient treatment and relapses. An eminent psychiatrist believed membership to be helpful to the following types of patient:

> People who are abnormally reserved, solitary, and shy and who find it difficult to adapt themselves to a normal social life.
>
> People who have had treatment at a mental hospital, such as a leucotomy operation, and who may need about a year's rehabilitation before they are completely fit.
>
> People who are constitutionally unstable and who find it hard to fit into life but can be kept in their jobs with a minimum of psychiatric treatment and help.

Parents, as part of child guidance, might also join these clubs.

Mr. Snow urged the Minister of Health to make known the general principles underlying these clubs and their economic applications as a means of relieving congestion in the existing mental hospitals; and also to provide grants for research.

Mr. ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, said it was an encouraging fact that over 60% of the patients in our mental hospitals were voluntary patients. For some time mental hospitals had been developing the work of welfare clubs, both inside and, to a more limited extent, outside the hospital. The clubs could be of immense value, particularly on the welfare and aftercare side—and indeed to some extent on the preventive side—but it would, he thought, be a mistake to over-emphasise their possibilities as an alternative to hospital or outpatient clinics. There was clearly some difference of opinion on this question between the medical experts who took the view expressed by Mr. Snow and those who took the view that the actual treatment side should be concentrated in hospital and outpatient clinics. That did not necessarily detract from the value of the work done by the clubs, but suggested that we were not likely to reduce greatly pressure on hospitals and outpatient clinics by the development of more clubs. So far we had little experience of the working of these clubs outside the hospital perimeter. The health authorities and the regional hospital boards were studying this problem both in London and elsewhere, but at the moment it was not possible to commit the Ministry of Health to any expenditure on these projects, or to guarantee that they could exert pressure on the local authorities or hospital boards. They felt that clubs arising naturally from the local health authorities and the regional hospital boards were more likely to be successful than any proposals originating nationally from the Ministry. He was, however, much interested in the proposals which had been raised and he could assure Mr. Snow that they would be given sympathetic consideration.

QUESTION TIME

Sterilisation

Mr. W. L. WYATT asked the Home Secretary whether his attention had been drawn to the case of a Mrs. Kindred who was put on probation in Birmingham on Jan. 27 after the bench had been informed that she had agreed to be sterilised; and whether he would set up a committee to inquire into the desirability or otherwise of amending the law with regard to sterilisation.—Mr. CHUTER EDE replied: I am informed that the court in deciding to put Mrs. Kindred on probation were not influenced by the information given to them that she was willing to be sterilised and that they made no reference to it in pronouncing their decision. Certain aspects of this question of sterilisation have already been considered by a Departmental Committee appointed by the Board of Control which reported in 1934. The general question of birth-control was considered by the Royal Commission on Population. It would not appear that any useful purpose would be served by setting up a further committee. Mr. WYATT: As the committee to which the Home Secretary referred strongly recommended that sterilisation should be legalised in certain cases, and as it is important that this should be done urgently, is it not time to consider introducing legislation to this end?—Mr. EDE: No, Sir. The matter is highly controversial and involves, I think, very serious infringement of the liberty of the subject. I am not prepared to introduce legislation.

Young Offenders

Replying to a question Mr. EDE stated: Provisional figures for the year 1949 for England and Wales showed that 24,872 boys and girls under the age of 14, and 15,064 aged 14 to 17, were found guilty of indictable offences and dealt with in magistrates' courts. The corresponding figures for 1948 were 26,715 and 16,991, and for 1947, 21,152 and 13,861. The decreases in 1949 as compared with 1948 were 1843 and 1927, or 7% and 11%.

Political Meetings in Hospitals

Mr. J. A. BOYD-CARPENTER asked the Minister of Health whether it was with his knowledge and consent that the South West Metropolitan Hospital Board issued instructions that parliamentary candidates were not to be allowed to address gatherings on hospital premises.—Mr. BEVAN replied: Hospital boards had discretion on this matter and my consent was not required. It is not possible to make a general uniform arrangement in this matter because of the difference in accommodation at different hospitals, and of the different kinds of hospitals. I therefore thought it was wise to leave it to those in charge, who could vary the practice with the needs of the case.

N.H.S. *Prescription Charge*

Mr. M. C. HOLLIS asked the Minister whether it was still proposed to proceed with the plan for charging 1*s*. on prescriptions; and if he had now decided what was the definition of a prescription.—Mr. BEVAN replied: I am not in a position to add anything to previous announcements on this subject. Lieut.-Colonel WALTER ELLIOT: When will the Minister be able to make any announcement on this subject and let us know when the Prime Minister's instructions are to be fulfilled?—Mr. BEVAN: This is a matter which will be assimilated in the Budget statement.

Shortage of School Dentists

Mr. BARNET JANNER asked the Minister of Education whether he was satisfied that sufficient numbers of dentists would now be available for schools throughout the country.—Mr. GEORGE TOMLINSON replied: No, Sir; in January last the school dental service employed the equivalent of 738 full-time dentists by comparison with 921 in 1948, when the service had fully recovered from the effects of the war. Although last year the net loss was very serious, there were nevertheless over 100 new entrants and I hope that the negotiations for a Dental Whitley Council now proceeding will lead to a settlement of salaries and the restoration of the service to its former efficiency.

Hospital Accommodation for the Chronic Sick

In answer to a question Mr. BEVAN stated that according to the latest information, which relates to the summer of 1949, there were 6114 chronic sick patients awaiting admission to hospital in England and Wales. In October, 1949, 5508 chronic sick beds were unoccupied for lack of staff.

Contributors to National Insurance

In answer to a question Dr. EDITH SUMMERSKILL, Minister of National Insurance, stated that in July, 1949, about 24 million persons had registered under the National Insurance Act. The total population of Great Britain aged 15 and over was about 38 million, but this figure included a considerable number of married women, pensioners, and others who are under no obligation to contribute.

Obituary

CHARLES MONTAGUE CHADWICK

M.A., D.M. OXFD, F.R.C.P.

Dr. C. M. Chadwick, consulting physician to Leeds General Infirmary, died at Tunbridge Wells on March 11 at the age of 96. He was elected to the fellowship of the Royal College of Physicians in 1896 and he was the third most senior fellow.

The association of the Chadwick family with Leeds General Infirmary goes back unbroken for over a hundred years, for his father, another Charles Chadwick, was physician there from 1842 to 1871. A fine portrait of him still hangs in the medical school. The younger Charles was educated at the University of Oxford and the London Hospital. After graduating B.M. in 1883 he continued his studies at the schools of Leipzig and Vienna. In 1892 he was elected assistant physician to the Leeds General Infirmary, and two years later he became full physician. He was also on the staff of the Leeds Public Dispensary. From 1896 to 1897 he was joint lecturer in forensic medicine in Leeds, and the following year he was appointed professor of materia medica, pharmacology, and therapeutics in the Victoria University, the precursor of the University of Leeds. He is still remembered as an excellent clinical teacher. He retired from all his appointments in 1905.

FRANK CUNINGHAME COWTAN

C.B., C.B.E., M.R.C.S.

Air Vice-Marshal F. C. Cowtan, who died at his home at Farnham on March 5 at the age of 61, was one of the men who in the first difficult days of the service gave substance to the medical branch of the Royal Air Force.

Born in Kensington, he was educated at St. Paul's School and St. Thomas's Hospital. After qualifying in 1912 he joined the R.A.M.C. and for his services in France and later in Mesopotamia during the 1914–18 war he was four times mentioned in despatches. In 1916 he was appointed D.A.D.M.S. to Sir Matthew Fell, who writes: "It was in Basra in the summer of 1916 that I first saw Cowtan when he came to replace my D.A.D.M.S. who was sick. I knew nothing of him personally, but in a very few days found that I had struck a winner. Medical administrative affairs up and down the Tigris were in a rather hectic state that year but Cowtan settled down at once. He was not afraid of hard work and his natural gift for administration and orderly mind were of immense help to me. From the first, I found him a delightful companion, and chuckled when he sometimes firmly but politely drew my attention to what he called 'your irregular methods, Sir.' Later when he came and told me that he would like to transfer from the R.A.M.C. to the new medical service of the Royal Air Force I was glad to do what I could to help him, for I knew what he was worth to the new service in its infancy."

This led to Cowtan's appointment as medical training officer at Halton with the rank of squadron-leader.

In his new service he rose steadily. From 1926 to 1928 he was deputy P.M.O. in Iraq. A period of staff duty at the Air Ministry followed, till he was appointed to the command of Princess Mary's Hospital at Halton. While he was P.M.O. of Middle East command he was invalided home, and the beginning of the late war found him as P.M.O. Coastal Command. In 1943 he held the same appointment to Fighter Command, and he was appointed C.B. In 1944, as P.M.O. to SHAEF he took part in organising the medical arrangements for D-day. His last appointment was P.M.O. to Bomber Command and he retired in 1945 owing to ill health. He was appointed C.B.E. the following year. From 1941 to 1945 he was honorary surgeon to the King.

A colleague writes: "All who have had the happy experience of associating with Cowtan recall a man of steady purpose, of well-judged approach to all problems, deep loyalty, and love of country. His example in correctness of dress and bearing are clearly remembered."

In 1915 he married Miss Nora Kennedy. She survives him with a son and a daughter.

HAROLD FREIZE STEPHENS

M.R.C.S.

Dr. Freize Stephens, formerly medical superintendent of Coleshill Hall Institution for Mental Defectives, Birmingham, died on March 9 at his home at Coleshill.

He was born in 1885 in Madras, where his father, Daniel Freize Stephens, was on the staff of the Public Works Department, and his mother, Dr. Grace Stephens, was physician to the Maharanee of Gwalior.

After qualifying from Guy's Hospital in 1912, he joined the staff of the Royal Earlswood Institution. In 1916 he went abroad to serve in France, Iraq, and Persia as a regimental medical officer, later becoming consultant in mental diseases to the Northern Command, India. In 1922 he became deputy medical superintendent at the Manor Hospital, Epsom, and he spent the rest of his life working among mental defectives. His gifts for organisation received a wider scope when in 1929 he was appointed medical superintendent of the newly opened Coleshill Hall Institution for Mental Defectives, founded by the corporation of Birmingham.

During the next twenty years Coleshill Hall increased under his administration from an institution with 300 beds to one with over 1000. Many of the senior members of his staff remained with him through the whole of his superintendentship. In 1937 the converted and modernised public-assistance institution known as the Marston Green Homes was opened as a branch of Coleshill Hall, and later up-to-date workshops for the teaching of handicrafts and trades, and three modern pavilions for young children, were set up. The system of daily employment of men and women patients outside the institution was extended. J. C. R. writes: "In his scheme of training, Dr. Freize Stephens gave an important place to physical exercises, organised games, and Scout and Guide work, and the annual sports days and the holiday camps were outstanding examples of his cult of open-air training and his belief in the importance of the team spirit. Optimistic and progressive, he was inspired by the belief that his duty lay in restoring as many as possible of his patients to their places in the outside world, and to this end he increased the scope of parole and of licence. In every aspect of his work he continued to impress the stamp of a forceful personality. Despite his failing health he kept his enthusiasm and his unsparing energy to the last, and he was planning fresh advances, when his final illness forced him to retire."

A man of many interests and activities, he was often consulted when other colonies for mental defectives were being planned. At the time of his death, he was chairman of the Northern and Midland division of the Royal Medico-Psychological Association, and he had served on several of the subcommittees of the association. He also did much work for the Mental Health Association.

In the reports of the National Council on Mental Hygiene (1926–27) he wrote on the causes of mental disorder, and he had also contributed to our columns papers on the treatment of persistent offenders and on research in mental deficiency. His series of articles on the nursing of mental defectives is appearing at present in the *Nursing Mirror*.

Dr. Freize Stephens leaves a widow and three sons, of whom the eldest is a medical officer of the Colonial Medical Service in Northern Rhodesia, the second a medical student, and the third a lieutenant in the Royal Navy.

Notes and News

HOSTELS FOR COMMONWEALTH AND AMERICAN STUDENTS

Since 1940 our kinsmen and friends in the Commonwealth and in the United States have sent us £80 million worth of food gifts, including 75 million parcels sent as gifts to people in this country and 130 million lb. through the Commonwealth Gift Centre to schools, hospitals, almshouses, and so on. Now we are to be given a chance to show our gratitude for their kindness through the National Thanksgiving Fund which the Lord Mayor of London has opened. The proceeds of the fund are to be used chiefly to develop a centre in London for Commonwealth and American students. The plan is to erect an £800,000 building for married and women students on the opposite side of Mecklenburgh Square to London House, a residential hall for men students from the Commonwealth; this will be close to the main London University buildings, the Inns of Court, the British Museum, and the great teaching hospitals. It is also planned to reconstruct the Georgian houses on the east side of the square for men students from America at a cost of £250,000 and to set aside £600,000 for the upkeep and maintenance of these two buildings and of London House. A further £150,000 will go to the overseas students' hall in Scotland, at Edzell in Angus. If the fund proves big enough £200,000 will be shared between the Royal Empire Society, the Victoria League, the Overseas League, the Dominions' Fellowship Trust, and the English-Speaking Union to help them in their work for students and other visitors from overseas.

To carry out this plan, about £2 million in all will be needed. Donations should be sent direct to the Lord Mayor of London, The Mansion House, London, E.C.4, marking the envelope National Thanksgiving Fund, or handed in at any bank or post office.

FOOD IN THE EARLY YEARS

Good feeding is a pleasure at any age. Between the ages of 1 and 5 it is a duty as well. In 1942 the Ministry of Health published a pleasant booklet designed to help those in charge of groups of young children " to plan and prepare balanced, attractive and varied meals." A revised edition[1] has now been issued, in which the recipes make use of the greater variety of foodstuffs which have become available since the first appeared. The text gives general advice on the feeding of preschool children, and on their emotional as well as their nutritional needs. They dislike sloppy dishes, and they like food to look agreeable. They enjoy helping to get a meal ready, handing round the vegetables, and helping themselves with a spoon from the dish. They prosper when meals come regularly, when they have been active in the fresh air before meal times, when dining conditions—and the adults in charge—are peaceful and pleasant. Overtired and flustered adults do not encourage good digestion. This matters, for the alimentary tract is adept at forming habits, whether good or bad.

University of Oxford

The vice-chancellor has appointed Dr. Alice Stewart, deputy director of the Institute of Social Medicine, to carry on the duties of the professorship of social medicine for Trinity term, 1950.

Prof. H. E. Sigerist, formerly director of the Institute of the History of Medicine, Johns Hopkins University, will deliver the James Bryce lecture on Thursday, June 1, at Somerville College. He is to speak on the Latin Medical Literature of the Middle Ages.

University of London

The title of fellow of University College has been conferred on Dr. Charles Singer, professor emeritus of the history of medicine in the university.

Mr. H. J. Eysenck, PH.D., has been appointed to the readership in psychology, with special reference to psychiatry, tenable at the Institute of Psychiatry.

University of Sheffield

Dr. S. E. Dicker has been appointed lecturer in physiology.

University of Manchester

On May 17 the honorary degree of D.SC. is to be conferred on Mr. V. E. Negus, and on Lord Boyd-Orr, F.R.S.

University of Leeds

Dr. Georgiana Bonser and Dr. L. L. Dmochowski, who are at present lecturers in the department of experimental pathology and cancer research, have been appointed readers in cancer research.

University of Edinburgh

During the summer term Dr. Douglas Guthrie, lecturer on the history of medicine, will deliver a series of lectures entitled a Retrospect of Medicine and Science. The lectures will begin on April 18 and they will be held at the University New Buildings, Teviot Place.

Scottish Conjoint Board

On March 16 the following were admitted to the licentiateship of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow:

Audrey J. J. Abel, Maureen M. Aylmer, John Bonner, R. F. Caddell, Harry Coll, Maureen Coneghan, Phyllis Connor, J. H. A. Craig, B. K. A. Crawford, D. McD. Cruickshank, Margaret S. Curley, S. I. Davidson, G. S. Fiddler, J. A. Fleming, W. G. French, Emily A. Friel, R. A. Gelfer, Iona J. Godson, Philippa D. Harrison, D. M. Hesslegrave-Jackson, Robert Hogg, Leslie Huddlestone, R. A. Ingles, T. F. McC. Jackson, Mary W. A. Jamieson, R. G. Kibbey, A. W. Laing, Claude Langman, Charles Lipp, W. R. McKenzie, H. D. Malasky, Margaret McN. Montgomerie, D. G. Muldoon, Mary H. Murray, Wilma Nield-Faulkner, Charles Randall, Louis Robinson, H. L. Sandler, Sat Dev Sethi, Ellis Sopher, F. C. Van-Coller, John White, G. C. Wilson, Eileen M. Wolstenholme, Harold Woolfson.

Faculty of Anæsthetists

Dr. John Gillies will deliver the second Joseph Clover lecture at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, on Wednesday, March 29, at 5 P.M. He is to speak on Anæsthetic Factors in the Causation and Prevention of Excessive Bleeding during Surgical Operations.

Society of Chemical Industry

The annual general meeting of the food group will be held on Wednesday, April 12, at 6 P.M., at Burlington House, London, W.1. At 6.30 P.M. Prof. S. Zuckerman, F.R.S., will give an address on Pounds, Dollars, and Calories.

Cardiology Congress

The first International Congress of Cardiology is to be held in Paris from Sept. 3 to 9. It is being organised by the Société Française de Cardiologie. The secretariat may be addressed at 19, rue Hautefeuille, Paris, VI.

International Congress of Dermatology

The tenth International Congress of Dermatology will be *held in London during the summer* of 1952, under the presidency of Sir Archibald Gray. Further information may be had from Dr. G. B. Mitchell-Heggs, Institute of Dermatology, St. John's Hospital for Diseases of the Skin, Lisle Street, Leicester Square, London, W.C.2.

Newsholme Lectures

Sir Henry Cohen will give the first Newsholme lectures at the London School of Hygiene, Keppel Street, W.C.1, on May 22, 23, and 24 at 6.15 P.M. He has chosen as his subject the Clinical Contribution to Public Welfare. The lectureship was created by the late Sir Arthur Newsholme, under a trust, and he laid down the following range of subjects: the application of anatomical and physiological teaching to the maintenance of health; the application of clinical teaching to the prevention of illness as it affects the hospital patient; and the effective curtailment of and recovery from illness.

Sheffield Regional Pædiatric Conference

The second regional pædiatric conference was held on Feb. 25 at the Children's Hospital in Sheffield. Dr. J. Lorber spoke on the Circulation of C.S.F. in Tuberculous Meningitis, and Dr. S. Doxiadis on Allergic Inflammations. Dr. C. Harvey, gave a survey of Congenital Heart Lesions in a School Health Service, and Dr. J. Emery illustrated the histological characteristics of the normal maturation of the pancreas in the child. At the end of the meeting Prof. R. S. Illingworth showed a film on the Development of Locomotion in Infancy.

---

[1] The Feeding of Children from One to Five Years. London: H.M. Stationery Office. 1949. Pp. 16. 6*d*.

Institute of Sociology

At a meeting to be held at Burlington House, W.1, on Tuesday, March 28, at 5.30 P.M., Mr. Geoffrey C. Tyndale, K.C., will speak on Children in the Divorce Court.

Postgraduate Course in Rheumatism

The Empire Rheumatism Council are holding their spring weekend course at the Apothecaries' Hall, Black Friars Lane, London, E.C.4, from April 28 to 30. Further particulars may be had from the secretary of the council, Tavistock House (N), Tavistock Square, W.C.1.

Hunterian Society

The Hunterian prize for 1949 has been awarded to Dr. S. M. Rivlin for his essay on the Treatment of Varicose Veins and their Complications. The council have chosen as the subject for the 1950 essay the Diagnosis and Treatment of Irritating Rashes. The competition is open to all general practitioners. Further details may be had from the hon. secretary, Mr. Clement Francis, 75, Wimpole Street, London, W.1.

Fellowships in Cancer Research

The British Empire Cancer Campaign invites applications for senior fellowships, tenable for seven years with a salary of £2000 rising to £2600, and for junior fellowships, tenable for three years, with a salary of £1000 rising to £1200. Further particulars will be found in our advertisement columns.

Medal in Dermatology

The examination for the Chesterfield medal will be held at the Institute of Dermatology, St. John's Hospital for Diseases of the Skin, Lisle Street, London, W.C.2, on Monday, Tuesday, and Friday, April 17, 18, and 21. Further particulars may be had from the secretary of the institute.

Wessex Rahere Club

The spring dinner of this club, which is open to all Barts men living in the south-west of England, will be held at the County Hotel, Taunton, on Saturday, April 29. Mr. J. B. Hume will be the guest of honour. Further information may be had from the secretary, Mr. A. Daunt Bateman, 3, The Circus, Bath.

Association of Hospital Launderers

It is proposed to form an association for hospital laundry managers. Those interested are asked to get in touch with Mr. G. E. Beckett, laundry adviser to the South-Western Regional Hospital Board, who may be addressed at the laundry department of the Bristol Royal Hospital, Royal Infirmary Branch, Bristol, 2.

Course on B.C.G.

A course for doctors on Tuberculosis in Children and the Use of B.C.G. is being held at St. Thomas's Hospital Medical School, London, S.E.1, from April 18 to 21. Sir Robert Young will give the opening address, and other speakers will include Dr. B. G. Thompson, Dr. W. L. Yell, Dr. A. E. Brown, Dr. Marcia Hall, Prof. Frederick Heaf, Dr. K. Neville Irvine, Dr. Wilfrid Sheldon, Mr. J. A. Chomeley, and Dr. F. J. Bentley. Further information may be had from the secretary of the Tuberculosis Educational Institute, Tavistock House North, Tavistock Square, W.C.1.

N.A.P.T. Essay Prize

The National Association for the Prevention of Tuberculosis is offering a prize of 100 guineas for an essay on the improvement of the control of tuberculosis throughout Britain. The competition is open to doctors of ten years' standing who are working as tuberculosis officers, chest physicians, or sanatorium medical superintendents in the United Kingdom. The competition is open until March 1, 1951, and further details can be had from the Secretary-general, N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1.

Peckham Health Centre Appeal

The members of the centre, which closed a week ago, have formed themselves into an association and have issued an appeal for assistance in establishing the centre as an institute of human biology and so continuing the Peckham experiment. The association asks for money so that the centre may reopen before the specially trained staff find employment elsewhere. Donations should be sent to the appeals secretary, Mrs. E. Purser, 1, Belfort Road, London, S.E.15.

Medical Art Society

The annual exhibition of the society will be held at Walker's Galleries, 118, New Bond Street, London, W.1, from April 17 to 29. The annual dinner will be held at Kettner's Restaurant at 7 P.M. on April 17. Further particulars may be had from the hon. secretary, Dr. Henry Wilson, 142, Harley Street, W.1.

Hospitals Renamed in Liverpool Region

At a meeting on March 2, the Liverpool Regional Hospital Board agreed that the names of institutions should be changed as follows: City Hospital East, Liverpool, to Rathbone Hospital; Green Lane Isolation Hospital, Ormskirk, to Ormskirk Children's Hospital; Fazakerley Sanatorium to Aintree Hospital; and Barrowmore Sanatorium to Barrowmore Hospital.

International Cancer Congress

The fifth International Cancer Congress will be held in Paris from July 15 to 22, at the time of the commemoration of the 50th anniversary of the discovery of radium by Pierre and Marie Curie. The work of the congress will be divided into three main sections: biology and experimental work; pathological, clinical, and therapeutic aspects; and social medicine. Further information may be had from the secretariat, Union Internationale contre le Cancer, 6, Avenue Marceau, Paris, VIII.

Maternity Services in Northern Ireland

Dame Dehra Parker, the minister of health and local government, is to set up a health advisory committee on maternity services as she considers that maternity services in Northern Ireland should be reviewed by people with first-hand experience. This announcement followed a motion by the Opposition urging the minister to bring the law relating to midwives into line with the Midwives Act, 1936, in England. The minister said she had every sympathy with the terms of the motion, and had decided that steps must be taken to put the midwifery services on a full-time footing.

International Federation of EEG Societies

This federation was founded, in the form of an international committee, at the international meeting held in London in 1947. A tentative organisation was set up, with the international journal *Electro-encephalography and Clinical Neurophysiology* as its official organ, and two working committees were formed—one on technique and another on terminology. At the Paris meeting last year a more formal organisation was established with a legal constitution in close liaison with UNESCO. The official title of the new body is the International Federation of Electro-encephalography and Clinical Neurophysiology. The following officers were elected and will hold office until the third International Congress, to be held in the United States in 1952: honorary president, Prof. E. D. Adrian, O.M.; president, Dr. Herbert H. Jasper; vice-presidents, Dr. Robert S. Schwab, Mr. W. Grey Walter, D.SC.; Dr. Fritz Buchtal; treasurer, Dr. Antoine Rémond; and secretary, Dr. Henri Gastaut, 149, Prom. de la Corniche, Marseilles, France.

Royal Society

The list of those appointed to the fellowship includes: Prof. B. P. BABKIN, M.D., D.SC., physiologist, McGill University, Montreal, for his work on secretion by the digestive tract and conditioned reflexes; W. J. ELFORD, PH.D., biophysicist, National Institute for Medical Research, London, for his researches on viruses, particularly on methods of determining virus size; C. A. HOARE, D.SC., protozoologist, Wellcome Laboratories of Tropical Medicine, London, for his work on parasitic protozoa, especially the trypanosomes; A. J. P. MARTIN, M.A., PH.D., biochemist, National Institute for Medical Research, for his work on the development of liquid-liquid partition chromatographic methods of chemical analysis; R. A. MORTON, D.SC., professor of biochemistry, University of Liverpool, for his studies on the chemistry and biochemistry of the fat-soluble vitamins; R. J. PUMPHREY, PH.D., professor of zoology, University of Liverpool, for his researches on the sense organs and central nervous system of animals, particularly for his work on hearing in insects and man; Prof. H. E. SHORTT, C.I.E., M.D., D.SC., head of the department of parasitology, London School of Hygiene and Tropical Medicine, for his work on protozoal diseases; R. L. M. SYNGE, PH.D., biochemist, Rowett Research Institute, Aberdeenshire, for his application of the principle of partition chromatography to the separation of amino-acids and peptides.

Royal College of Physicians

Dr. B. T. Parsons-Smith, will deliver the Lumleian lectures on Tuesday and Thursday, April 11 and 13, at 5 P.M., at the college, Pall Mall East, S.W.1. His subject is to be Cardiac Failure.

London Cinchona Bureau

Sir Philip Manson-Bahr has been appointed director of the bureau at 10, Princes Street, London, S.W.1. The post was formerly held by the late Prof. C. A. Bentley.

London County Medical Society

A clinical meeting of this society will be held at St. Nicholas' Hospital, Tewson Road, Plumstead, S.E.18, on Monday, April 17, at 3 P.M. Inquiries should be sent to the hon. secretary, Mr. J. Gabe, F.R.C.S., St. Alfege's Hospital, S.E.10.

Infantile Paralysis Fellowship

The fellowship has bought the Lantern Hotel at Worthing. It is not to be used as a convalescent home but as a seaside hotel for people with infantile paralysis, and it is to be specially adapted to meet their needs.

Presentation to Mr. Mullally

Members of the staff of the Hospital of St. John and St. Elizabeth and colleagues of Mr. G. T. Mullally met on March 15 to present him with an illuminated address, a barometer, and a cheque. He is retiring after nearly 30 years' service on the staff of the hospital.

Jamieson Memorial Fund

At the suggestion of a group of his former colleagues in Leeds, a Jamieson Memorial Fund has been instituted in memory of John Kay Jamieson, for many years professor of anatomy and dean of the faculty of medicine in the University of Leeds. The fund is administered by a representative committee, and subscriptions have been invited from former students of the university who were taught by Professor Jamieson, as well as from old friends and colleagues. It is proposed to found a scholarship or prize with which Professor Jamieson's name will be associated. The fund will close on April 30.

Appointments

ALDRIDGE, J. S., M.R.C.S.: asst. county M.O., Devon.
BICKNELL, FRANKLIN, D.M. Oxfd, M.R.C.P.: physician to outpatients, French Hospital and Dispensary, London.
BORTHWICK, J. B., M.B.E., M.B. Edin., F.R.C.P.E.: asst. physician to Scottish Borders hospital group.
CRONIN, J. D., M.B. Lond., F.R.C.S.: orthopædic surgeon, French Hospital and Dispensary, London.
DICKSON, MARY, M.R.C.S., D.P.H.: asst. M.O. for maternity and child health services, County of Northampton.
DIMSDALE, HELEN, M.D. Camb., F.R.C.P.: consultant neurologist, Royal Free Hospital, London.
FRANK, J. R., M.B. Edin., F.R.C.S.E.: assistant surgeon to Scottish Borders hospital group.
GREENWOOD, J. M., M.D. Manc., D.P.H.: consultant physician in charge of chronic sick wards at, Newholme and Withington Hospitals, Manchester.
HOWARD, STANLEY, M.B. Lpool: senior asst. M.O.H. for City of Bradford in connection with the care and aftercare scheme.
KEITH, A. M., M.B. Aberd., F.R.F.P.S., F.R.C.S.E.: consultant orthopædic surgeon, Royal Alexandra Infirmary, Paisley.
LANCASTER, GEOFFREY, M.B. Manc.: appointed factory doctor for Ambleside district.
LAND, F. T., M.B. Glasg., F.R.F.P.S., D.L.O.: consultant surgeon in charge of E.N.T. Hospital, Glasgow.
MACALISTER, C. L. O., M.B. St.And., F.R.C.S.E.: consultant in genito-urinary surgery mainly at hospitals in No. 15 (Bradford A) hospital management committee group.
MCEWAN, TOM, M.D. Glasg., F.R.F.P.S.: consultant physician as *second asst. physician (physician to the outpatient dept.)*, Royal Infirmary, Glasgow.
MAYER, A. L. R., M.B. Glasg.: chief M.O., National Sanatorium, Benenden, Kent.
RAFTERY, J. D., D.PHIL. Oxfd, B.SC. Witw'srand, F.R.C.S.: asst. visiting orthopædic surgeon, Addington Hospital, Durban, S. Africa.
VALENTINE, A. A., M.B. St.And.: psychiatrist (S.H.M.O.), Royal Scottish National Institution, Larbert.
VALENTINE, G. H., M.B. Brist., M.R.C.P.: consultant pædiatrician, Peterborough area.

Liverpool Regional Hospital Board:

CONROY, P. B., M.R.C.S., D.A.: consultant anæsthetist, hospitals in North Liverpool and adjoining areas.
DAVIDSON, J., M.B., D.A.: whole-time consultant anæsthetist, hospitals in North Liverpool and adjoining areas.
EGAN, G. P., M.D. N.U.I., D.P.M.: consultant deputy superintendent, Rainhill Hospital.
LIPTON, SAMPSON, M.B. Lpool, D.A.: consultant anæsthetist, hospitals in North Liverpool and adjoining areas.

Diary of the Week

MARCH 26 TO APRIL 1

Monday, 27th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. R. T. Johnson: Carotid Ligation for Intracranial Aneurysms.

Tuesday, 28th

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Mr. A. K. Monro: Abnormalities of the Cutaneous Circulation in the Lower Limb.

Wednesday, 29th

ROYAL COLLEGE OF SURGEONS
5 P.M. Dr. John Gillies: Anæsthetic Factors in the Causation and Prevention of Excessive Bleeding during Surgical Operations. (Clover lecture.)
MEDICAL RESEARCH COUNCIL
10 A.M. (*London School of Hygiene, Keppel Street, W.C.1.*) Prof. A. Bradford Hill, D.SC. 2 P.M. Prof. J. R. Squire, Dr. Alice Stuart: Scientific Method in Field Surveys.
INSTITUTE OF PSYCHIATRY, Maudsley Hospital, S.E.5
4.30 P.M. Dr. E. Stengel: Postgraduate lecture-demonstration.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. C. A. Boucher: Accident Prevention in the Home.
UNIVERSITY OF GLASGOW
8 P.M. (Department of Ophthalmology.) Dr. T. Wilson: Modern Methods of Investigation.

Thursday, 30th

MEDICAL RESEARCH COUNCIL
9.30 A.M. Sir Frederic Bartlett, F.R.S., 2 P.M., Prof. W. E. Le Gros Clark, Mr. T. Bedford, D.SC.: Improvement of Human Performance by Laboratory Studies.
WESTMINSTER MEDICAL SCHOOL, S.W.1
5.30 P.M. (Meyerstein lecture-theatre.) Clinicopathological meeting on two cases of Hodgkin's Disease complicated by Tuberculosis.
INSTITUTE OF DERMATOLOGY
5 P.M. Dr. H. Gordon: Pitfalls in Treatment.

Friday, 31st

MEDICAL RESEARCH COUNCIL
9.30 A.M. Dr. Donald Hunter, Dr. J. M. Barnes. *2 P.M., Dr. C. M. Fletcher: Investigation of Health Hazards.*
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES
8 P.M. (11, Chandos Street, W.1.) Dr. A. R. Martin: Principles of Penicillin Therapy.

Births, Marriages, and Deaths

BIRTHS

BARTLEY.—On March 17, at Poole, the wife of Dr. Christopher Bartley—a son.
BLAKELOCK.—On March 16, at Lincoln, the wife of Dr. L. H. Blakelock—a daughter.
CALDER.—On March 11, at Windsor, the wife of Dr. Alan Calder—a son.
CHANCE.—On March 12, in London, the wife of Dr. Ivor Chance—a daughter.
FOXELL.—On March 12, at Southampton, the wife of Dr. Alan Foxell—a son.
GRETTON-WATSON.—On March 9, in Chester, the wife of Dr. B. G. Gretton-Watson—a daughter.
HALE.—On March 13, in London, the wife of Dr. John Hale—a son.
HALL.—On March 14, at Northampton, the wife of Dr. R. N. Hall—a son.
LITTLE.—On March 14, at Bristol, the wife of Dr. Brian Little—a son.
MOONEY.—On March 14, in Manchester, the wife of Dr. Terence Mooney—a son.

MARRIAGES

BRACEWELL—YATES.—On March 11, in London, Graham Acton Bracewell, M.B., to Pamela Margaret Yates.
FORBES—GRUBERT.—*On March 15, in Berlin*, Duncan Forbes, M.B., captain, R.A.M.C., to Susanne Grubert.
MACKENZIE—ANDERSON.—On March 11, in Glasgow, Ian Carville Keith Mackenzie, M.B., to Anthea Mary Anderson.
SMITH—TURNER.—On March 18, at Bishop's Stortford, Irvine Smith, M.A., F.R.C.S., to Kathleen Turner, M.B.

DEATHS

CHADWICK.—On March 11, at Tunbridge Wells, Charles Montague Chadwick, M.A., D.M. Oxfd, F.R.C.P., aged 96.
CURWEN.—On March 15, at Hove, Eliot Curwen, M.A., M.B. Camb., F.S.A., aged 84.
DINGLEY.—On March 16, at Myddle, Salop, Lionel *Alfred* Dingley, M.D. Lond., F.R.C.S., aged 61.
FEARNHEAD.—On March 11, Thomas Fearnhead, M.R.C.S., of Lytham, aged 83.
KELLY.—On March 12, at Hanchurch, Stoke-on-Trent, Peter Kelly, M.B. Glasg.
LANE.—On March 16, at Eastbourne, Gordon Joseph Lane, M.D. Dubl.
SPRAGUE.—On March 11, Cecil Gordon Sprague, M.R.C.S., surgeon captain, R.N. retd.
STEVENSON.—On March 16, in Belfast, Howard Stevenson, B.A., M.B. R.U.I., F.R.C.S.I.
WARD.—On March 11, at Rochampton, Arthur Blackwood Ward, C.B.E., D.S.O., M.B. Camb., aged 79.

PAIN IN THE UPPER LIMB FROM MECHANISMS IN THE COSTOCLAVICULAR SPACE

F. A. R. Stammers
C.B.E., Ch.M. Birm., F.R.C.S.
PROFESSOR OF SURGERY, UNIVERSITY OF BIRMINGHAM

This paper is based on a personal series of 40 cases and began as a postgraduate lecture * on the costoclavicular syndrome. However, since my purpose was to examine and discuss all types of discomfort, from pain, paræsthesia, or sensory change in the precise distribution of a particular nerve, to something vaguer and more widespread, with or without motor or vascular phenomena, I think the present title is better.

Such conditions as osteo-arthritis and fibrositis of the cervical spine, osteo-arthritis of the shoulder and acromioclavicular joints, subacromial bursitis, brachial neuritis, retropulsed cervical disc (usually 5th or 6th), and even spinal-cord tumour or Pancoast's tumour, may account for very similar symptoms. Yet it should be possible, by careful examination and investigation, to differentiate all these from the group which I wish to consider now.

Twenty-five years ago it was accepted that the presence of a cervical rib or band might be the cause of discomfort confined precisely to the distribution of the ulnar nerve; but once the symptoms extended beyond this boundary the case was no longer understood, and it was often labelled as neuritis, fibrositis, or osteo-arthritis. Thanks to many observers it is now realised that many factors operating in the costoclavicular space may play a part in causing discomfort of much wider distribution than that of the ulnar nerve.

THE CERVICAL RIB

Cervical rib is mentioned in the writings of Galen and of Vesalius. Adson and Coffey (1927) stated that it was present in 0·056% of 500,413 cases X-rayed at the Mayo Clinic for various reasons; and Steiner (1943) found it in 0 05% of 38,105 patients. Gruber's (1869) classical paper grouped cervical rib into four kinds:

1. Short, with head, neck, and tubercle represented.
2. One that extends beyond the transverse process of the 7th cervical vertebra, possessing a body as well as a head, neck, and tubercle, but ending in a free tip.
3. Like (2) but with the tip attached to the 1st thoracic rib, either by a fibrous band or by an articulation.
4. A complete rib, attached in front to the costal cartilage of the 1st thoracic rib.

Halbertsma (1858) claimed that if the cervical rib was over 5·6 cm. long it supported the subclavian artery, but that if less than 5·1 cm. long it did not so support it. Gruber did not agree with this; and my own observations show that much depends on the height to which the arch of the artery rises in the neck.

Cervical rib may be unilateral or bilateral, and if the latter more often asymmetrical than symmetrical (fig. 1). Walshe et al. (1944) believe this asymmetry of the thoracic inlet to be a dominant fact in producing symptoms.

According to most textbooks the average age of onset of symptoms is about 20 years, but in my own cases the age tended to be around 30 years, the youngest case being 11 years old, and the oldest 63 years old. All agree that the majority are females.

Signs.—The rib may be large enough to present as an obvious and palpable supraclavicular swelling (figs. 2 and 3), and the subclavian artery may be pushed forward by it, its pulsations being visible and even simulating an aneurysm. In such a case a thrill can sometimes be felt by the examining finger and a bruit heard. In most cases the rib cannot be seen, though the supraclavicular fossa may look shallow. The rib can usually be palpated, either as a definite bony prominence or by the shallow and firm feeling it gives to the supraclavicular fossa. Pressure in the fossa may reproduce the discomfort of which the patient complains.

Symptoms

Symptoms are classically divided into sensory, motor, and vascular, and each and all are often worse when in bed, or during certain activities involving the arm.

Sensory.—The typical sensory symptoms are pain or paræsthesia within the ulnar area of the hand: examination may show sensation to be normal or it may reveal interference with one or more modalities of sensation. A less common form of sensory symptom in cervical rib (though more common when initiated by the other factors in the costoclavicular space) is a much more widespread discomfort involving hand, forearm, arm, especially the outer side, the shoulder, and occasionally the same side of the thorax and neck. Kinnier Wilson (1913) explained this by suggesting that when the inner cord of the brachial plexus is stretched over the cervical rib, the fibres destined to form the medial component of the median nerve may also be affected, so that the general threshold to pain of the whole plexus may thus be lowered. The fact that rest in bed with the affected arm in a sling relieves the pain favours this theory.

Motor.—The typical affection is weakness and wasting of the muscles of the hand supplied by the ulnar nerve. But here again, there is a less common manifestation of cervical rib—once more pointed out by Kinnier Wilson (1940)—namely, paralysis of two of the muscles of the thumb, the abductor and the opponens, sometimes accompanied by anæsthesia of the outer side of the base of the thumb.

Vascular.—*Vaso-spastic phenomena*, which are less common than sensory or motor symptoms, may present themselves in two ways—Raynaud-like attacks, and attacks of prolonged cyanosis and coldness of the hand, with an accompanying sensation described by the patient as "stiffness of the hand," during the course of which she appears to be able to achieve only "slow motion" movements of the fingers. As I shall show, the absence or presence of vascular symptoms, and the type of symptoms experienced, depend among other things on whether the arch of the subclavian artery is a high or low one.

Walshe et al. (1944) suggest that *aneurysm* should be not uncommon, but in my experience it is exceedingly rare. The third part of the subclavian artery is commonly somewhat wider than the second part, and this might be misinterpreted as an aneurysmal dilatation. On one

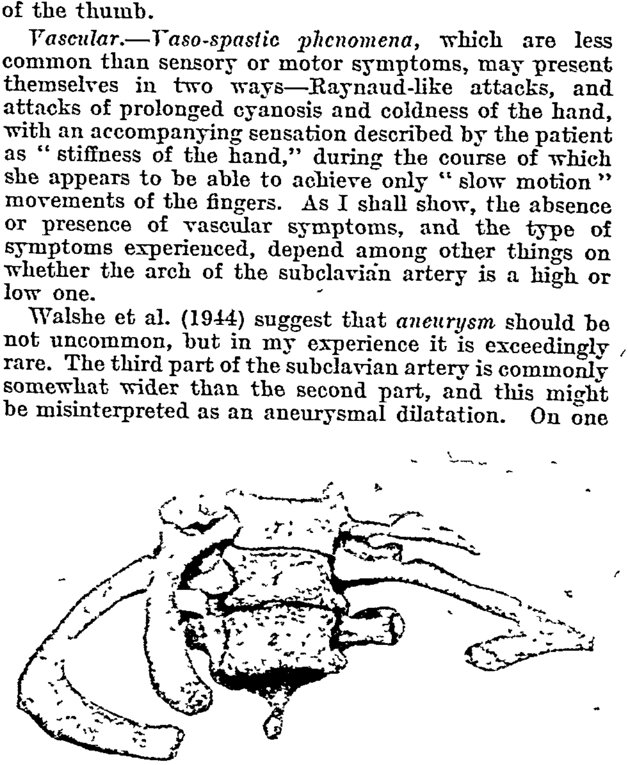

Fig. 1—Skeleton of bilateral cervical ribs. They are characteristically asymmetrical, which probably accounts for the asymmetry of the thoracic inlet (Schultze).

---

* Given on Nov. 8, 1949, before the Edinburgh Post-Graduate Board for Medicine.

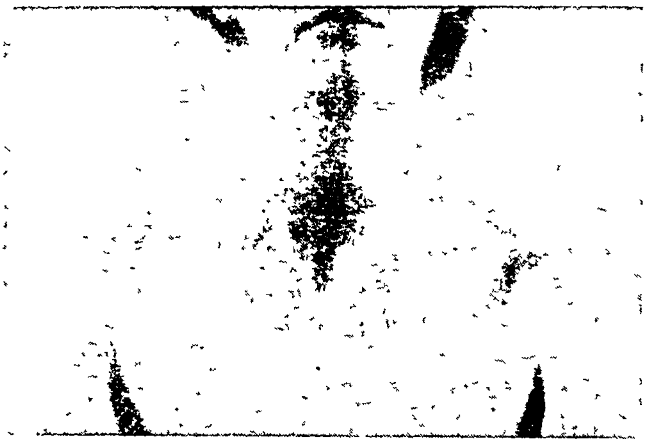

Fig. 2—A young woman with an easily visible cervical rib on the right side.

occasion I encountered a subclavian artery the substance of which had undergone change to such an extent that when, after attempting to control a fine spray of bleeding from the third part, I applied a pair of mosquito-forceps laterally, they bit a hole into the artery, and when, to control the consequent much worse hæmorrhage, I applied forceps across the artery, they cut through it as if through perished rubber, so that the open end of the second part now bled furiously. A forceps applied to the first part held normally, and a ligature controlled the situation satisfactorily. It is unfortunate that, in the excitement of the moment, no specimen for microscopy was taken; but that the wall was grossly abnormal, though not in the least dilated, was certain; and it must have represented the very earliest stage in the development of an aneurysm.

Cases of cervical rib developing finger-tip gangrene are said to owe this feature to emboli from small *thrombi* in the subclavian artery. One case within my experience showed much more dramatic vascular embarrassment than this.

A woman of 63, when snapping string while packing her Christmas parcels, felt a sudden pain in the shoulder region, and the arm became useless, benumbed, and cold. I first saw her three weeks later, when the arm was still cold, pulseless, cyanosed, slightly œdematous, anæsthetic, and almost completely paralysed, and on examination she presented the largest pair of cervical ribs I have yet seen. There seems no doubt that in the sudden movement of snapping string she caused trauma to her subclavian artery, perhaps at an atheromatous patch. There was no evidence of accompanying venous thrombosis.

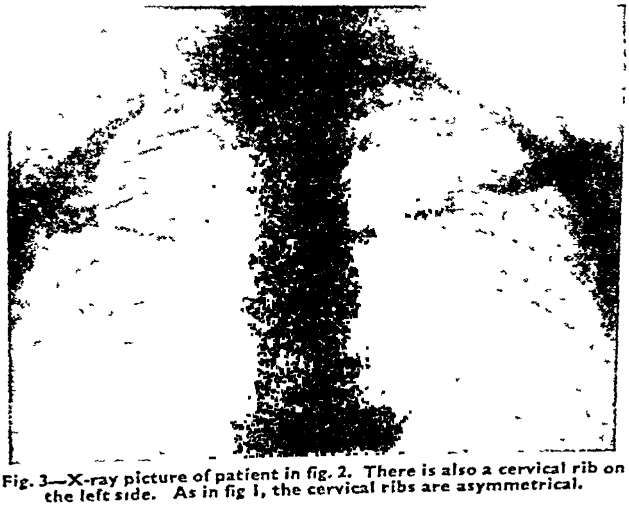

Fig. 3—X-ray picture of patient in fig. 2. There is also a cervical rib on the left side. As in fig 1, the cervical ribs are asymmetrical.

THEORIES OF VASCULAR INVOLVEMENT

Eden (1939) and Lewis and Pickering (1934) maintained that vascular symptoms were the result of direct pressure of rib or band on the artery; and D. M. Morrissey and I have observed that this certainly is true where a cervical rib articulates with the 1st thoracic rib just behind the scalene tubercle—when a highly arched subclavian artery is pressed against the prominence of the articulation by the action of the scalenus anticus (fig. 4).

Telford and Stopford (1931) have argued that in some people most of the sympathetic fibres destined to supply the arterial tree of the upper limb travel in the inner cord of the brachial plexus; and that if they have a cervical rib or band, these sympathetic fibres will be stimulated by pressure, thus inducing arterial spasm. In support of this hypothesis—which was based on the examination of the plexus of a patient suffering from cervical rib who died from some intercurrent disease—they point out that it explains why the spasm begins at the point where the axillary artery becomes the brachial. On the other hand, Blair et al. (1935) had a similar opportunity of examining a brachial plexus after death but found the sympathetic fibres widely distributed throughout the plexus. Walshe et al. (1944) believe that vascular symptoms are due to actual nipping of the artery between the clavicle and 1st rib or cervical rib. More recently, Telford and Mottershead (1947) suggest that the axillary artery is nipped by the two heads of the median nerve.

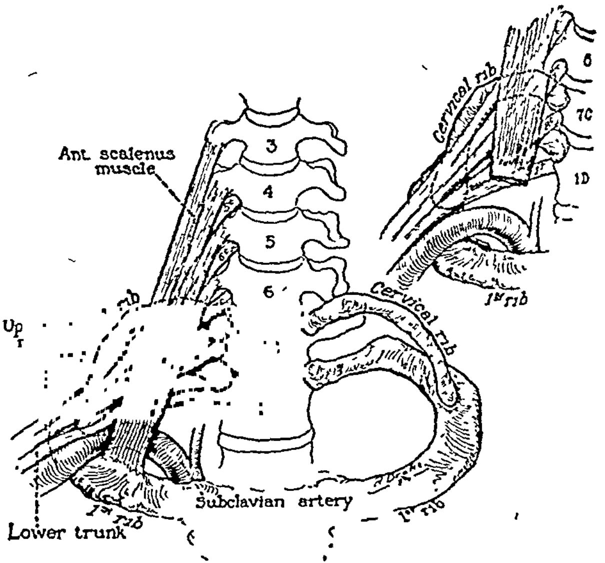

Fig. 4—When the subclavian artery arches higher above the clavicle than shown here, it lies against the prominence of the articulation of cervical and 1st dorsal ribs, and is pressed against it by the action of the scalenus anticus.—Taken from Adson's article in Christopher's Textbook of Surgery.

OTHER FACTORS

Postfixed Plexus

Minor variations certainly occur in the make-up of the brachial plexus; we have already seen that the distribution of the sympathetic fibres to the plexus varies from patient to patient. But, as I understand it, a postfixed plexus is one that is derived from cervical 6, 7, 8, and thoracic 1 and 2, instead of from one segment higher. I think it likely that less decided variations than this occur in its composition, and that some of the other anatomical variations to be mentioned distort or kink a normally constituted plexus.

Inner Border of Scalenus Medius

On a number of occasions I have encountered a tight, sharp, fibrous band in the inner border of the scalenus

Fig. 5—Radiograph of a "bottle necked" person.

medius, with the inner cord of the plexus or the highly arched subclavian artery kinked against it. The normal action of the scalenus anticus presses these structures against this band, and the action of carrying heavy parcels stretches them across it. It is a most striking thing, and must be cut or excised in order to leave the plexus and artery quite free from distortion due to it. Leriche has for many years advocated cutting the band. Strands of Sibson's fascia are also sometimes sufficiently prominent to present sharp edges against which the neurovascular bundle may be kinked.

Abnormal 1st Thoracic Rib

The rib may be bifid, or joined to the 2nd thoracic rib by a synchondrosis, or it may be thickened as the result of healing of a stress fracture; and this thickening may cause symptoms. White et al. (1945) maintain that it is impossible to differentiate an abnormal 1st rib from a cervical rib unless the so-called "moving jaw" technique of radiography is employed. In this technique the patient is instructed to open and close the mouth rapidly during exposure, and this makes it possible for all cervical vertebræ to be seen and counted on an anterior-posterior plate.

Enlarged 7th Cervical Transverse Process

Normally, the transverse process of the 7th cervical vertebra is shorter than that of the 1st thoracic, but it may be as long or even longer—when symptoms may result. Annersten (1947) believes that the important factor is compression of artery or cord between scalenus anticus and the enlarged 7th cervical transverse process; he refers to an "index," based on a comparison of lengths of the two processes. Where symptoms suggest some mechanical interference with the plexus or artery in the costoclavicular space, an enlarged 7th transverse process supports this diagnosis. It is usually accompanied by a fibrous band, often in the scalenus medius.

The Scalenus-anticus Syndrome

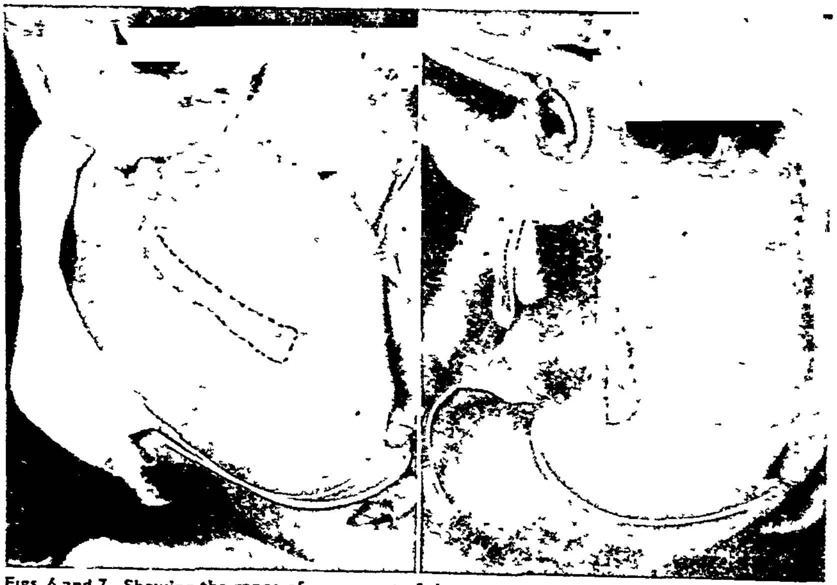
As Annersten says, "symptoms of brachial plexus compression used to be regarded as due to a cervical rib." Then Adson and Coffey suggested that the action of the scalenus anticus was all-important, and the expression "scalenous-anticus syndrome" was introduced. If this muscle is capable of producing the syndrome it is hardly surprising that symptoms should develop since—as Walshe et al. (1944) point out—being an extra-respiratory muscle, it contracts about 23,000 times in 24 hours. Other workers, too, attribute to the muscle a major rôle in symptoms of compression of the plexus: Ochsner et al. (1935) suggest that its overaction irritates the nerve supply, throwing the muscle into spasm and thus leading to further compression; they quote Naffziger as claiming that spasm of the muscle causes pressure on structures behind it; Donald and Morton (1940) state that in most of 40 cases of brachial plexus compression, they found the muscle to be sclerotic and hypertrophied; some authors declare the hypertrophy to be three to four times normal; Eden (1939) discovered fibrous bands in the region of the scalenus anticus. The occurrence of these latter I can myself confirm, but I regard the theory of hypertrophy, apart from general muscularity, as exaggerated.

All this may be true, but, whether the muscle is hypertrophied or normal, I cannot see why symptoms should be produced unless there is something abnormal behind the plexus or subclavian artery against which the extra-respiratory action of the scalenus anticus can compress these structures; such abnormalities are cervical rib, abnormal 1st thoracic rib, fibrous inner border of scalenus medius, or the normal dropping of the thoracic inlet almost constant in women after the menopause. For these reasons, scalenectomy is effective.

Costoclavicular Syndrome

There still remains a group of patients suffering a variety of symptoms which, in the absence of something more definite, have been ascribed to actual nipping of the plexus or artery, or both, between the clavicle and the 1st thoracic rib. The following are examples:

1. During the recent war it was not uncommon to find certain young recruits who could not wear the Army pack without gross discomfort in the arms. That the complaint was genuine was confirmed by the observation that the hands became congested, cyanosed, and benumbed, and the arms became useless, so that they had to be helped off with their pack, after which they quickly recovered. These men were usually slightly built, often of the weedy type, with sloping shoulders and what has been termed "bottle neck" (fig. 5). When one examined the supraclavicular space "things felt superficial" and one could almost palpate the 1st thoracic rib. I have no doubt that the broad straps of



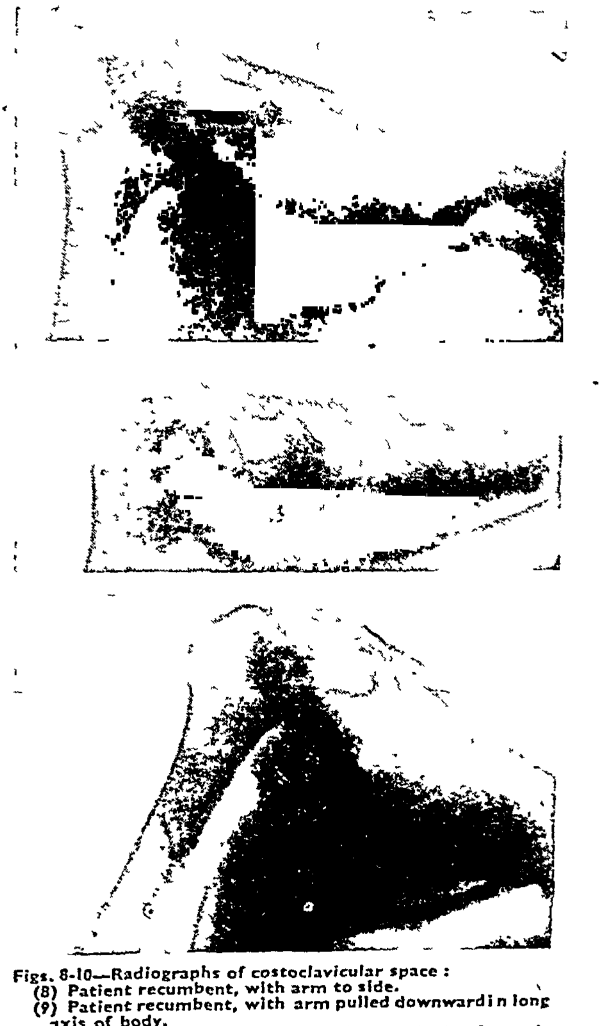
Figs. 6 and 7—Showing the range of movement of the outer end of the clavicle between forward and backward movements of the shoulder girdle.

the pack actually pressed the plexus against the rib, and the clavicle against the subclavian artery and vein. I saw two young men who developed anæsthesia of little and ring fingers and mild wasting of the interosseous muscles; and the condition became known in our unit as "pack palsy." After several weeks of Army food, outdoor life, and shoulder-muscle exercises, these cases were able to tolerate their packs.

2. Walshe (1945), during the war, called attention to the development of numbness, tingling, and uselessness of the fingers in women obliged to do their own housework and shopping. It was common enough in pre-war days among washerwomen and charwomen, and was often called neuritis. But during the war, some housewives, normally accustomed to domestic help and the services of errand boys, had to take on these labours themselves, often standing with heavy baskets in food queues after nights of fitful sleep interrupted by air-raids. He attributed the disorder to falling of the shoulders—*the result of fatigue and loss of muscle tone*—and a consequent nipping of structures between clavicle and rib; and he called it "acroparæsthesia."

3. Pommerenke and Risteen (1944) published 4 cases of pain and weakness of the hand resulting from patients being changed during operation from the flat to the Trendelenburg position, the shoulder-pieces being rather hurriedly applied; and 2 similar cases occurred in my own hospital.†

4. I know of a rowing man who has been troubled in recent years because he finds that he develops Raynaud-like phenomena in both hands after rowing about half a mile. There are no cervical ribs: may this from athletic hypertrophy of muscles?



Figs. 8-10—Radiographs of costoclavicular space:
(8) Patient recumbent, with arm to side.
(9) Patient recumbent, with arm pulled downward in long axis of body.
(10) Patient recumbent, with shoulder actively elevated.

There is no doubt that the general conformation the thoracic inlet, together with its relation to clavicle, determines whether certain circumstan e.g., change of occupation, decline in health, fatigue, an age-change—lead to pulling, kinking, or nipping of som part of the brachial plexus or subclavian vessels. In 1943 d'Abreu published a significant case of a girl, 29 years old, with an enlarged 7th cervical transverse process on the right side and a cervical rib on the left. These were symptomless, until a right-sided thoracoplasty was performed for phthisis of the right lung Three years later she developed vascular and nervous symptoms typical of those of cervical rib. d'Abreu *suggests that this was brought about by the artificial* falling of the shoulder after the thoracoplasty. The adoption by man of the upright position has inevitably been blamed by several authors, including Russell Hugo Patterson (1940), and recently Lambert Rogers (1949).

Telford and Mottershead (1947) have studied in students the effect on the radial pulse of various movements of the arm. Morrissey, of my department, has repeated these experiments, obtaining almost the same results:

(*a*) Almost any muscular man can obliterate his radial pulse by active adduction of the arm against the trunk.

(*b*) The action of retraction (bracing of the shoulders)—the same action as that used in rowing—obliterates the pulse in over 60% of normal men and women.

(*c*) Active abduction with extension diminishes or obliterates the pulse in about 50% of normal people.

(*d*) The important part of Adson's test is the deep inspiration after turning the extended head to the affected side, *thus causing the scalenus-anticus muscle to contract.* Indeed, the mere act of holding the breath in inspiration will, in some subjects, obliterate the pulse.

Figs. 8–10 show how the angle between the clavicle and the 1st thoracic rib or cervical rib varies with different movements: and figs. 6 and 7 show the wide range of movements of the outer end of the clavicle. We have also observed on the dissected cadaver the effect on the costoclavicular space of forceful downward pull of the arm—as happens when a heavy weight is carried with the arm by the side. The movement of the clavicle is more than a simple downward displacement, which would approximate clavicle and rib: the clavicle also rotates forwards, thus falling away from the rib and thereby widening the costoclavicular space. In retraction of the shoulder the clavicle not only moves backwards, radially on the sternoclavicular joint, but also rotates axially in a counter-clockwise direction, thus further approximating itself to the rib.

DIFFERENTIAL DIAGNOSES

In summary it can be said that pain or discomfort in the upper limb may be brought about by a number of factors operating in the costoclavicular space:

1. Cervical rib or band; and particularly the bony prominence produced by the type of rib which articulates with the scalene tubercle of 1st thoracic rib.
2. *Enlarged 7th cervical* transverse process.
3. Fibrous inner edge of scalenus medius.
4. Abnormal 1st thoracic rib.
5. The scalenus anticus muscle certainly plays a part, but it is the presence of some other abnormality behind it that enables it to do so.
6. (*a*) *The level to which* the subclavian artery rises in the neck; (*b*) the exact make-up of the brachial plexus; (*c*) the distribution of sympathetic fibres in the plexus; (*d*) the natural slope of the shoulders—the "bottle necked" folk.
7. Anatomical changes: (*a*) fatigue and general atonia of muscles; (*b*) unaccustomed exercise and weight-bearing, as in young recruits; (*c*) the natural falling of the thoracic inlet in women at about the age of 40.

Some other conditions which have to be considered when making the differential diagnosis can usually be ecognised by full clinical examination and investigation. They are:

---

† Since this lecture was given, two more papers on this subject have appeared, by M. R. Ewing and by L. G. Kiloh (*Lancet*, Jan. 21). They suggest that the Trendelenberg position, abduction of the arm, and curare are especially responsible

(a) Osteo-arthritis of cervical spine.
(b) Fibrositis of neck muscles.
(c) Retropulsed cervical disc.
(d) Cervical spinal cord tumour, progressive muscular atrophy or syringomyelia.
(e) Osteo-arthritis or rheumatoid arthritis of shoulder or acromioclavicular joints.
(f) Subacromial bursitis.
(g) Raynaud's disease.
(h) Other peripheral vascular disease.
(i) Brachial neuritis.
(j) Tardy ulnar palsy.

Finally, it must be appreciated that a cervical rib may cause no symptoms at all; but, as a corollary, that in addition to a cervical rib, there may be present other lesions capable of producing discomfort in the arm. For instance, during the past year I have had one patient with cervical rib suffering from ulnar-nerve phenomena in the hand of the same side, yet at the same time having rheumatoid arthritis in the same shoulder; and a second case with cervical rib, osteo-arthritis of the cervical spine, and fibrositis of the neck muscles. Such cases must be particularly carefully assessed, and trials of the effect of treatment applied to such conditions as arthritis and fibrositis may succeed in deciding whether or not the abnormal rib plays any part.

TREATMENT

Where a cervical rib is associated with signs and symptoms of ulnar-nerve involvement in the hand, there is no doubt that in the absence of lesions outside the costoclavicular space, exposure of the subclavian artery, brachial plexus, and the rib should be undertaken. Operation should certainly be advised when the subclavian artery is pushed forward by the rib and seen as a large pulsating prominence just above the clavicle, since, though aneurysm is uncommon, it may develop. Much more important in these cases is the risk of vasospastic symptoms in the hand, and even of sudden thrombosis of the main artery.

In cases of clear-cut ulnar-nerve involvement without a true cervical rib but with an elongated transverse process of the 7th cervical vertebra, I think the region should be explored, since there is likely to be a tight edge-like band in the inner border of the scalenus-medius muscle against which the more anterior scalene is pressing some part of the plexus or, when it is highly arched, the subclavian artery. I am again supposing that investigation has failed to discover any of the extracostoclavicular-space lesions mentioned under differential diagnosis.

For all the remainder—that is to say, those patients complaining of vaguer and more widespread discomforts, whether associated with cervical rib or elongated 7th cervical transverse process or not—I believe the correct procedure is to prescribe shoulder-shrugging exercises and to support the affected arm in a sling so as to widen the angle between the clavicle and the thoracic inlet. It may be necessary for the really fatigued patient to commence treatment by complete bed rest for a week, and to build up her general health by tonics and diet. If no improvement follows in four to six weeks' time, I believe that it is justifiable to explore the costoclavicular space.

OPERATION

Details of operation are well described in all books on operative surgery. The important thing is to see that the inner cord and the artery both lie free from kinking or stretching by a sharp edge, be it cervical rib or inner border of scalenus medius. A necessary preliminary is to cut the anterior scalene muscle, after which the structures under review can be fully explored. In order to give the best exposure the patient's head is usually extended and turned to the opposite side, and the arm is drawn downwards in order to depress the clavicle. This position inevitably puts the anterior scalene on the stretch, and it may be this fact that has misled some into speaking of spasm of that muscle: at any rate, the position exaggerates the part played by it. Having severed the muscle, as much of the cervical rib is removed as is necessary to leave the cord or artery quite free; or, where there is a sharp edge to the scalenus medius, this is excised. Careful hæmostasis is essential, since hæmatoma is very liable to develop, and its subsequent organisation may result in adhesions in the space. For this reason, it is wise to employ a glove drain for the first 48 hours.

PROGNOSIS

Cases of cervical rib or band, or of scalenus-medius band, accompanied by pain and motor or sensory changes in the ulnar distribution in the hand, or of vascular phenomena, are usually relieved of their pain immediately. Paralysis and sensory change cease to progress, but recovery is incomplete. Vascular phenomena are also usually immediately relieved. The vague discomforts of the "costoclavicular" group are relieved by physiotherapy in about half the cases, and scalenectomy or severance of a band cures about half of the remainder.

I am grateful to Dr. O. Smith for the radiographs, and to Mr. Dee, of the photographic department, for the reproductions.

COMPLICATIONS OF ULCERATIVE COLITIS

J. M. Rice-Oxley
B.M. Oxfd, M.R.C.P.
MEDICAL REGISTRAR, RADCLIFFE INFIRMARY, OXFORD

Sidney Truelove
M.D. Camb., M.R.C.P.
FIRST ASSISTANT TO NUFFIELD PROFESSOR OF CLINICAL MEDICINE, OXFORD

Ulcerative colitis presents formidable problems in management to physician and surgeon alike. Its many and varied complications add further to these difficulties. These complications have been described by Bargen (1929) in 693 cases at the Mayo Clinic, and since then by Hurst (1935), Streicher (1938), Willard et al. (1938), Jackman et al. (1940), and Ricketts and Palmer (1946).

An account is given here of the complications encountered in 129 patients admitted to the Radcliffe Infirmary, Oxford, in the eleven years 1938–48. Though small compared with some of the American series, this seems to be the largest number of cases so far described from one hospital in England, and the disease seems to be commoner in the Oxford area than in many other regions.

The complications found were as follows:

Complication	*No. of cases*	*Incidence %*
Cutaneous lesions	12	9·3
Arthritis	7	5·4
Stricture	7	5·4
Fæcal fistulæ	5	3·9
Carcinoma of colon or rectum	4	3·1
Perforation	4	3·1
Stomal ulcers	4	3·1
Perirectal abscess	2	1·5
Conjunctivitis	2	1·5
Prolapsed rectum	1	0·8
Biliary cirrhosis	1	0·8
Suprarenal hæmorrhage	1	0·8

CUTANEOUS LESIONS AND ARTHRITIS

A striking feature of the present series is the high incidence of skin and joint lesions, often occurring together. Bargen (1929) reported skin lesions in 2·5% and arthritis in 4% of his 693 cases. Hurst (1935) reported an incidence of 2·5% for both types of lesion in his 40 cases, and in the series of Willard et al. (1938) there were no skin lesions but 5 of the 63 patients developed arthritis. Ricketts and Palmer (1946) reported an incidence of 10% for surface lesions of skin and mucosa in 206 cases, but further analysis shows that less than half of these lesions were definitely associated with the ulcerative colitis.

We think it worth while to draw attention to these complications, both because they were often troublesome and because in some cases they had obscured the diagnosis before admission.

The types of skin rash were as follows:

Lesion	*No. of cases*
Erythema nodosum (3 with arthritis)	4
Erythematous rashes	2
Pustular rashes (1 with arthritis)	3
Purpura (with arthritis)	1
Ulceration of legs (with arthritis)	1
Urticarial rash	1

In 5 cases they were minor, transient, and, since all coincided with exacerbations of colitis, were largely overshadowed by the diarrhœa. In the remaining 7 cases, on the other hand, they appeared as major episodes, being accompanied by arthritis in 5 cases which will be described in detail.

Erythema Nodosum

Case 1.—A girl, aged 16, was first admitted in May, 1940, with six months' history of diarrhœa with blood and mucus in the stools. On admission she was pale and looked ill. Hb 48%. A barium enema showed loss of haustration in the distal colon, and sigmoidoscopy revealed changes characteristic of ulcerative colitis. There was some improvement in the patient's condition during the next five months, but in October, 1940, her temperature went up again and the diarrhœa became worse. A few days later she developed erythema nodosum on both shins, with pain and swelling of the right elbow and wrist. These passed off in the next month, but after a further month she had a second crop of erythema nodosum. She was finally discharged, still passing blood and mucus in her stools, in January, 1941.

In April, 1947, she was readmitted in another exacerbation, which had started three weeks previously. She again developed erythema nodosum affecting the hands, forearms, and legs, with pain and swelling of both knee-joints. The rash faded during the next week, but the relapse continued for another six weeks.

Case 2.—A woman, aged 21, first admitted in August, 1943, had had seven weeks of diarrhœa with blood and mucus in the stools in 1940 and further attacks in 1941 and 1942. When admitted in 1943 she was in a severe relapse, and an ileostomy was performed. The immediate result was satisfactory, but she continued to have relapses, and colectomy was advised but refused. She was readmitted in March, 1945, and May, 1946.

Her fourth admission was in October, 1946. Three weeks before, she had noticed a small red tender nodule over the left tibial tubercle, after which first her right and then her left ankle became swollen and painful. Ten days later the joint swellings had begun to subside, but five days before admission her left knee had become involved. On admission she had a temperature of 102°F, and shortly afterwards tender erythem tous nodules appeared on the dorsal aspect of both feet an the left shin. In the next fortnight the fever settled and th joint swellings subsided. The nodules turned bluish, and th was scaling of the overlying epidermis.

The patient has had numerous relapses since but with any great constitutional disturbance, and there has been n recurrence of the arthritis or skin lesions.

Case 3.—A woman, aged 39, admitted in April, 1940, h had diarrhœa since 1922. In 1925 she had been admitted t hospital in France with the diarrhœa and a rash; typhoid fever was diagnosed and she was in bed many weeks. The diarrhœa had continued. Two months before admission red hard tender non-irritating lumps had appeared on both her legs and hands. The lesions came in three successive crops, each crop going away without breaking down or leaving any scars. Accompanying the rash she had pain and swelling in the ankles, knees, fingers, wrists, and elbows, and fever. Her doctor had diagnosed rheumatic erythema. Her stools had increased in frequency and become offensive. By the time of admission her skin lesions had almost completely cleared, but the diagnosis of ulcerative colitis was confirmed by barium enema and sigmoidoscopy.

Case 4.—A woman, aged 67, was first admitted in November, 1944. In 1931 and 1937 she had had two short attacks of diarrhœa, with blood and mucus in the stools, lasting two and four weeks. In August, 1944, she again developed diarrhœa with blood and mucus in the stools. The diarrhœa continued, and a week before admission she developed red shiny slightly raised painless nodules round the knees. On the day of admission she noticed two small similar nodules on her right upper arm and left wrist. Some of these nodules had a slightly purplish discoloration, and the largest ones were tender on palpation. During the next month her diarrhœa improved and the rash on her legs vanished.

In January, 1947, she had another relapse and developed similar lesions. This time she went rapidly downhill and died in a month.

Bargen (1929) has commented on the simultaneous appearance of erythema nodosum and arthritis in several of his cases. Brooke (1933) reported the case of a woman of 23, who, during a relapse of ulcerative colitis, developed on her shins and arms lesions resembling erythema nodosum which finally broke down; the lesions cleared as the diarrhœa improved but recurred during the next relapse. Elitzak and Widerman (1941) have described 3 cases of erythema nodosum in 23 children with ulcerative colitis. The lesions differed from the form ordinarily described in that they appeared in successive crops for several weeks. Jackman et al. (1940) have reported erythema nodosum in 9 out of 871 patients with ulcerative colitis (1%), including 95 children.

The 4 cases which we have described were all in females, and in 3 of them joint swellings accompanied the skin lesions. The lesions all tended to appear in crops, and in 2 cases bluish discoloration was observed as they faded. None of the lesions broke down, though in one case the overlying epidermis scaled. In case 3 a previous exacerbation of diarrhœa fifteen years earlier, accompanied by a rash, had been diagnosed as typhoid—it is not known whether this diagnosis was correct. The skin and joint lesions accompanying the exacerbation for which she was admitted had been diagnosed as rheumatic by her own doctor. Since similar skin lesions occur as toxic eruptions in sulphonamide therapy, particularly with sulphathiazole, it should be mentioned that the appearance of the lesions could not be related to sulphonamide therapy in any of these cases.

As regards ætiology, all the lesions developed during an exacerbation of ulcerative colitis and were accompanied by fever. They were evidently a manifestation of the toxæmia and may well have been an allergic response to toxins present in the bowel, comparable to the production of erythema nodosum in primary tuberculous and streptococcal infections. It would be interesting to try the effect of the anti-histamine drugs on the lesions, but an opportunity has not yet arisen.

Ulcers of Leg and Arthritis

Case 5.—A man, aged 29, was first admitted in May, 1944. Attacks of diarrhœa had started in 1931, when he was 15½. The first attack had lasted three months. In 1935, in the third attack, the patient had had severe pain and swelling in the knees and ankles, and the arthritis had recurred in subsequent relapses. Since 1942 the relapses had been accompanied by ulcers on the ankles and feet.

When he was examined in May, 1944, he had an ulcer 1½ × ¾ in. and about ⅛ in. deep on his right foot just above the internal malleolus, blisters on the inner border of his right foot and on the sole of his left foot, and an inflamed area along the inner border of his left foot. Ankle movements were painful, and the right knee was swollen. His diarrhœa was severe and he was at times incontinent. During the next two months his diarrhœa improved and the ulcers almost healed. In August, 1944, while still in hospital, he had another exacerbation of diarrhœa and then developed a deep reddish-purple blister, ½ in. in diameter, just above the left internal malleolus. During the next two months the diarrhœa again improved and the skin lesions healed.

In April, 1945, he had another relapse, with recurrence of arthritis and ulceration of the feet. He was readmitted in July, 1945, when the relapse was almost over. At that time there were healing areas of ulceration just below the right external malleolus and on the dorsum and plantar surface of the left foot.

Ulceration of the legs during exacerbations of chronic ulcerative colitis have been described by Leishman (1949) and Butler (1948) in this country and by Jankelson and Massell (1936) and Felson (1941) in America. It is interesting to note that in case 5 arthritis began to complicate exacerbations of the diarrhœa many years before the skin lesions appeared, and that afterwards they appeared concurrently. In contrast to the cases of erythema nodosum, since this man's skin lesions were all confined to the feet, it is probable that, in addition to toxæmia, lowered skin resistance, perhaps secondary to vitamin deficiency, and repeated trauma were partly responsible for their production. It is significant that the most indolent ulcer on his right foot was at the site of a scar of a "cut down" for blood-transfusion, where the skin would be devitalised and particularly susceptible to infection.

Case 6.—A woman, aged 42, was admitted in June, 1943. Diarrhœa with blood and mucus in the stools had started in November, 1939. After fourteen weeks in the Royal Berkshire Hospital she had improved considerably but had continued to have four or five stools daily. In May, 1941, she had noticed that her legs felt heavy and swollen, with lots of little "bruisy spots like pinpricks." These had disappeared after four days, but in July, 1941, they had recurred and spread to her arms and back. The purpuric eruption was accompanied by pain and swelling of the knees, ankles, and right elbow, and at the same time her diarrhœa was worse, her bowels being opened 6–7 times daily. She had again been admitted to the Royal Berkshire Hospital, and the skin and joint lesions had cleared. In May, 1942, she had had another recurrence of the purpura on her face and trunk and her face had become so swollen that for four days she could not open her eyes. Purpuric hæmorrhages had continued to appear during the next two months, and her diarrhœa had been worse.

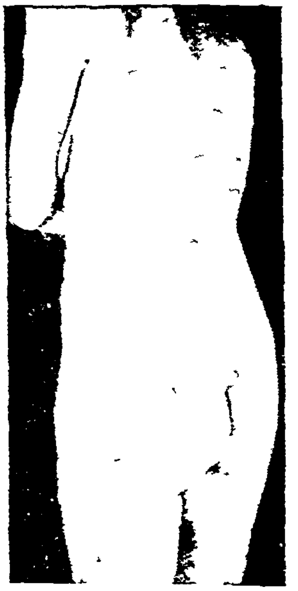

Fig. 1—Large ecchymosis on left chest and buttocks in a patient (case 6) with ulcerative colitis.

In June, 1943, her knees had become swollen and painful, and within twenty-four hours her shoulders and left elbow had also become involved. Two days later, bluish areas, at first the size of a shilling, had appeared on her trunk and limbs, and the joint swellings had subsided. The hæmorrhagic areas had become confluent, almost completely encircling her trunk and limbs. On her admission a few days later there were some recent purpuric spots on her forearms and hands, and brown stains of old outcrops were visible elsewhere on her body. On the back of her chest on the left side was a large ecchymosis 9 × 6 in., and there were similar ecchymoses over the buttocks and behind the left knee (fig. 1). The bleeding-time, coagulation-time, and platelet-count were all normal. A barium enema showed general loss of haustration, and proctoscopy a diffusely inflamed rectum. An atypical coliform organism was grown from her stools, and on injection into her arm this produced a profuse purpuric eruption. She was desensitised with a vaccine prepared from this organism, and her lesions cleared in the next three months.

In this case it will be noted that (1) the diarrhœa preceded the purpura by 1½ years; (2) the purpura and exacerbations of diarrhœa showed a seasonal incidence, beginning always in the early summer: and (3) the bleeding-time and platelet-count were normal, while the radiological and proctoscopic changes were those of ulcerative colitis. The purpura and arthritis were evidently an allergic reaction, and the question arises whether ulceration of the colon was another manifestation of this reaction or was the source of the antigen giving rise to it. It might be argued that the bowel changes producing bloody diarrhœa were due to purpura of the Henoch's type, and that a diagnosis of ulcerative colitis was unjustified. We feel, however, that the duration of the diarrhœa before the purpura appeared and the loss of haustration seen after the barium enema justify the diagnosis. Moreover, the fact that an organism isolated from the bowel could on injection produce a profuse purpuric eruption is evidence in favour of the colon being the source of the antigen sensitisation which gave rise to the purpura and arthritis. On the other hand, the seasonal incidence of the purpura and of the later exacerbations of the diarrhœa suggest rather that both symptoms were an allergic response to some separate antigen; those who believe that ulcerative colitis is an allergic disease will favour this view.

Generalised Exfoliative Erythema

Case 7.—A woman, aged 43, was admitted in February, 1944, with three months' history of severe diarrhœa with blood and mucus in the stools. Two weeks before admission she had developed a diffuse erythema on her trunk and limbs, most marked on the flexor surfaces. On admission the skin of her trunk was exfoliating, her general condition was poor, pulse-rate 106 per min., blood-pressure 80/60 mm. Hg, and she was mentally apathetic. Plasma-vitamin A and plasma-carotene levels were 54 I.U. and 27 I.U. per 100 ml.—both very low. The patient went rapidly downhill and died a week later. Necropsy showed gross ragged ulcerative colitis throughout the large intestine, and the sigmoid colon had ruptured in several places.

Unlike the other cases so far described, this woman's rash developed in the acute fulminating type of ulcerative colitis, and she died within three months of its onset. There was clear evidence of gross vitamin deficiency, and the rash was probably pellagrous.

OTHER COMPLICATIONS

Rectal Stricture

In all the 7 cases of rectal stricture this was severe and not just a narrowing of the colon such as is often seen after a barium enema in ulcerative colitis. In 4 cases the stricture was rectal, in 2 at the pelvirectal junction, and in 1 there were multiple strictures of the colon. In all 7 patients the colitis was of long standing, the average duration up to the discovery of the stricture being eleven years. In 4 cases the stricture was treated either by colostomy or ileostomy. In 2 cases it was found that a carcinoma had supervened on a chronic fibrous stricture. In 2 cases a stricture developed in

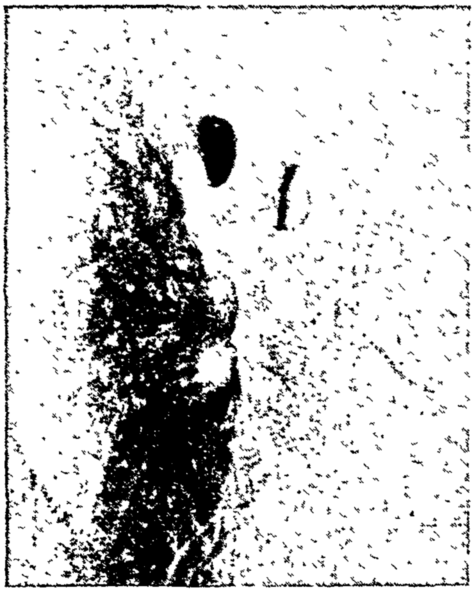

Fig. 2—Two fistulæ-in-ano in a patient with ulcerative colitis. Note absence of granulation tissue round the edges and of any tendency to heal.

the rectum after colostomy had been done for fæcal fistulæ.

Fæcal Fistulæ and Perirectal Abscess

Fistulæ proved a troublesome complication in 5 cases. There was a complete lack of any tendency to heal (fig. 2), and all required operation. In 4 cases the opening was perianal, and 2 of these had an ileostomy and 2 a colostomy; in 1 case colectomy was done later because discharge from the fistula continued after the first operation.

In the 5th case the fistula was abdominal in the vicinity of the left anterior superior iliac spine and communicated with the descending colon. Colectomy of the descending colon and splenic flexure was done and this fistula healed. Later the patient developed a rectovaginal fistula, and a colostomy was done in another hospital. When the patient was readmitted to the Radcliffe Infirmary two years later this fistula had also healed, but the rectal stricture already mentioned was found.

Ischiorectal abscesses developed without fistulæ in 2 further cases, both after ileostomy, done in one case as an emergency procedure in acute fulminating colitis, and in the other for rectal stricture. Both patients died.

Carcinoma of Colon and Rectum

Carcinoma is a recognised complication of ulcerative colitis, and the published reports have been reviewed by Lynn (1945), Johnson and Orr (1948), and THE LANCET (1950). The incidence in different series varies from 1·3 to 6·3%, the general incidence being about 2·5%, which is in close accord with our figure. Taking 40 cases of which there was a record, Johnson and Orr found that the ages of the patients developing carcinoma ranged from 18 to 69 years, with an average of 40·2 years, whereas the average age at which carcinoma of the colon of all kinds develops is 53. In our series the average age of the 4 cases was 37 years. The average duration of the disease before the development of carcinoma was estimated by Cattell and Sachs (1948) as nine years; in our series it was seven years.

Perforation

Perforation is a severe and generally fatal complication occurring in the most acute type of ulcerative colitis. It occurred in 3% of Bargen's (1929) cases, and 3·4% of those of Ricketts and Palmer (1946). In 3 of the 4 cases in our series it was a terminal event, but the 4th patient was saved by an ileostomy and suture of the perforation, and he is still alive. The duration of the disease before perforation was three months, four month and eighteen months in the fatal cases, and eighte months in the patient who survived. It is peculiarl difficult to diagnose, because it develops in a severel ill patient and is not accompanied by the dramat symptoms and signs which attend perforation at othe times.

Ulcers in the Mouth

Buccal ulceration was noted in 4 patients and caus great discomfort. In 2 cases the ulcers appeared durin relapses which were sufficiently severe for ileostomy t be carried out; in both cases the operation was successful and the ulcers healed soon afterwards. In the other 2 patients the ulcers also appeared during a bad relapse with fever and considerable constitutional disturbance In 1 of these cases, which occurred in the early days of penicillin, when it was still scarce, the stomal ulcer had been one of the most distressing features of the patient's illness for two months, but they cleared in a week after a course of systemic penicillin. In another relapse four years later the same patient developed an ulcer in her mouth while on penicillin, but it healed in two or three weeks. This seems to indicate that, though infection keeps these ulcers going once they have started, it is not the primary cause.

Conjunctivitis

Conjunctivitis occurred in 2 cases in several relapses, with skin lesions at the same time. Iritis or uveitis was noted in 5 of Bargen's (1929) cases, always with one or more other complications.

Rectal Prolapse

Prolapse occurred in 1 case in which ulcerative colitis had been present for more than ten years. It was associated with considerable spasm of the anal sphincter, and during relapses became sore and painful. The patient has had no further serious relapses since 1945 and, though he still has a slight prolapse, it does not trouble him and no operation has been necessary.

Biliary Cirrhosis

Hepatic cirrhosis was found in only 1 case—a patient of only 14 with no previous history of jaundice.

The patient was a boy of 14 in whom the colitis ran a particularly severe course, for he died seven weeks from its onset. For the last two weeks he was vomiting. Clinically the liver edge was palpable and hard, but there was no splenic enlargement.

At necropsy the liver was enlarged, weighing 1498 g., and of wooden consistence. There was well-marked fibrosis of the whole organ, with areas of hyperplastic liver tissue between the strands of connective tissue. The spleen showed an excess of fibrous tissue and weighed 294 g. Histologically the liver showed severe biliary cirrhosis, and the spleen a diffuse fibrosis throughout. The changes in the colon were those of severe ulcerative colitis, extending from the cæcum to the anus.

This single case may be considered a chance association, but cirrhosis as a complication of ulcerative colitis has been mentioned several times in published reports; in some of the cases, however, there were other possible causes for it. Thus Comfort et al. (1938) have reported 4 cases of long-standing ulcerative colitis associated with hepatic insufficiency, and Tumen et al. (1947) have described, in 151 cases of ulcerative colitis, 5 cases in which there was definite liver disease. In 4 of these the hepatitis was considered to be a complication of the colitis; in the 5th patient there was a previous history of alcoholism and dietary insufficiency in addition, which made it difficult to ascertain the prime cause. Two of these patients died within 16–22 months from the onset of the disease. In 2 other cases the disease was of the chronic continuous type, and in 1 other it was mild and intermittent. Ross and Swarts (1948) have observed 2 cases of jaundice and cirrhosis associated with ulcerative olitis. In one the patient became jaundiced two years fter the onset of diarrhœa and died five years later of iver failure, a nodular cirrhosis being found at necropsy. The other patient became jaundiced nine years after the nset of the ulcerative colitis and at laparotomy was ound to have cholecystitis and cholangitis, which may well have been responsible for the cirrhosis.

The importance of nutritional deficiency, especially protein deficiency, as a factor contributing towards liver disease is now fully realised. In ulcerative colitis loss of protein takes place in several ways. Large quantities of blood and mucus may be passed in the stools, and intestinal hurry may lead to impaired absorption. In severe cases there may be poor appetite and vomiting, as in the patient we have described, with the result that protein intake is reduced. Thus it is to be expected that the liver will become vulnerable; and in view of the severe toxæmia so often present it is surprising that liver damage is not a more common finding in ulcerative colitis.

Suprarenal Hæmorrhage

Hæmorrhage into the suprarenal gland developed in a particularly severe case, the patient dying in a month from the onset of the colitis.

At necropsy, ante-mortem thrombi were found in both suprarenal veins. Both suprarenal glands were moderately enlarged and very firm and tense, with bright-red blood on the external surface. On the cut surface there were numerous small triangular areas of hæmorrhage with their bases against the capsule, each measuring about 0·2–0·3 cm. in diameter. In the thicker part of the gland, where the pattern was more complicated, there appeared to have been a more generalised hæmorrhagic lesion.

This case suggests that suprarenal damage may be a factor contributing towards the dehydration and extremely rapid loss of weight often seen in the severe fulminating type of ulcerative colitis, and that cortical extract might be a useful adjunct to treatment.

Polyposis

The absence of a single case of polyposis in the colon presents a curious anomaly, for this almost invariably heads the list of complications in other series—e.g., Bargen (1929) 10%, Hurst (1935) 12·5%, and Jackman et al. (1940) 16·2%. The explanation may partly be that polyposis is primarily a sigmoidoscopic diagnosis and is present in long-standing cases. Though sigmoidoscopy was done at some time or other in almost all our cases, it was not done as a routine in the follow-up period. Nevertheless many patients were sigmoidoscoped at a stage when ulcerative colitis had been in progress for some years, and the absence of polypoidal changes must be regarded as unusual. Since closing this series we have personally observed 2 classical cases.

SUMMARY

The complications developing in 129 cases of ulcerative colitis are described.

Attention is drawn to the high incidence of skin and joint lesions, usually coincident. Seven of these cases are described in detail and the possible ætiological factors briefly discussed.

Four patients developed carcinoma of the colon or rectum, their average age being 37, compared with the average age of 53 at which carcinoma of the colon usually develops.

We wish to thank Prof. L. J. Witts and the physicians of the Radcliffe Infirmary, for permission to publish their cases, and Dr. F. G. Hobson for helpful criticism.

CHLORAMPHENICOL IN TYPHOID FEVER

R. A. GOOD
M.B. N.U.I., D.P.H.
MEDICAL SUPERINTENDENT, VICTORIA INFECTIOUS DISEASES HOSPITAL, WINCHESTER

R. D. MACKENZIE
M.B. Edin., F.R.C.P.E.
DIRECTOR, PUBLIC HEALTH LABORATORY, WINCHESTER

IN the outbreak of typhoid fever at Crowthorne, Berkshire, in the spring of 1949, some of the cases were admitted to the Victoria Infectious Diseases Hospital, Winchester. Through the coöperation of Dr. W. H. Bradley, senior medical officer, Ministry of Health, a supply of chloramphenicol was provided for the treatment of these patients. This was the first opportunity in this country of giving chloramphenicol under controlled conditions in typhoid fever. This antibiotic, which was originally obtained from cultures of *Streptomyces venezuelæ*, is now also prepared synthetically. It was first used successfully in scrub-typhus, but a chance observation by Smadel (Woodward et al. 1948) showed that it also possessed a specific therapeutic action in typhoid fever.

A total of 13 patients were admitted to hospital in Winchester, all being confirmed cases of typhoid fever. At first only enough chloramphenicol was available for treating 6 cases, so on Dr. Bradley's advice (Bradley 1949) the patients were divided into two groups: 6 (A, D, G, H, I, and J) to receive chloramphenicol, and 7 (B, C, E, F, K, L, and M) to act as controls. In the selection of patients for treatment a strict alternate-case method was adopted, no consideration being given to age, sex, date of onset, history of previous immunisation, or severity of illness. Later, however, when the chloramphenicol had proved its usefulness and was more plentiful, 3 of the control patients (F, K, and L), who had relapsed and were causing anxiety, were given the drug. The nursing and management were similar for all 13 patients.

The patients were admitted to hospital between May 2 and 4, 1949, between the 8th and 14th days of their disease. Specimens of fæces and urine were cultured daily, and blood-cultures and agglutinin estimations were made at intervals. Before the start of treatment positive stool-cultures had been obtained from all 13 patients, and all belonged to Vi-phage type E.1. Routine blood-cultures were not taken until after treatment had begun. Administration of chloramphenicol to the 6 selected patients began on the evening of May 5, when they were on average at the 13th day of disease. Further details of these cases are given in table I.

DOSAGE

Treatment was given, on the lines suggested by Woodward et al. (1948), for eight days, 4 g. being given in the first hour and followed by 0·25 g. two-hourly

* Days of disease. † Relapse.

until the temperature was normal and thereafter four-hourly for the rest of the course. The total dosage thus differed in the various cases according to the time taken for the temperature to return to normal. The average total dosage in the 6 cases for the eight days was 20·75 g.

PROGRESS OF PATIENTS TREATED WITH CHLORAMPHENICOL

The response to chloramphenicol was similar in all cases and characteristic. Within seventy-two hours the temperature and pulse-rate had returned to normal and there was a well-marked improvement in the general condition. The toxæmia and headache were relieved, the mental outlook became brighter, appetite increased, and the patients asked for food, which they ate with obvious enjoyment. Abdominal discomfort was soon relieved, and reflexes returned where they had been absent. One or more bulky stools were passed, this being followed in most cases by formed motions as reported by Douglas (1949).

Stool-cultures.—Cultures from the stools tended to become negative during the eight-day course of chloramphenicol. This happened in 3 of 6 cases and lasted from three to six days. Stools from all these patients later became positive again. A corresponding negative period was not found in any of the 7 controls. The results of these stool-cultures are given in table II.

Urine-cultures.—Positive urine-cultures were obtained from 3 of the 6 patients just before treatment started. In each case urine-cultures became negative within forty-eight hours of the start of treatment and remained negative throughout the course. All 7 controls gave positive urinary cultures on one or more days during the same period.

Blood-cultures.—Before their admission to hospital Dr. Norman Wood, of Reading, had isolated *Salmonella typhi* from the blood of 2 of the patients who subsequently received chloramphenicol and from 1 of the controls. Further blood-cultures were made four days after the start of treatment, when all 6 patients treated with chloramphenicol were negative, as were 5 of the 7 controls. Later (see table II) 4 of the 6 treated cases and 4 of the 7 controls became positive.

Relapses.—In 3 cases (D, G, and H) clinical recovery proceeded uneventfully, but case D became a temporary excreter and may possibly become a permanent carrier. Details of her case are given below. Cases A, I, and J, whose temperatures had been within normal limits for 23, 18, and 16 days respectively, all relapsed. In cases I and J the symptoms were severe, and, since they were accompanied by a return of blood infection, it was decided to give a second course of chloramphenicol. In case A the symptoms of relapse were mild and unaccompanied by a return of blood infection; so a second course was not considered necessary.

The relapses of cases I and J on the 35th and 33rd days of disease respectively ran a similar course. There were the usual rise in temperature and pulse-rate, headache, loose stools, vomiting, and abdominal discomfort. Positive blood and stool cultures were obtained from both, and case J also had a positive urine. Treatment was on similar lines to those originally adopted, and this occasion an average dose of 20·125 g. of chlor- phenicol was given in nine and a half days. The mperatures returned to normal in about forty-two urs, compared with seventy-two hours in the original urse of treatment. One or two bulky stools were ssed, the general condition improved rapidly, and both tients made an uninterrupted clinical recovery. The ools of these patients became negative during this cond course of treatment and did not again become ositive while they remained under observation. Blood-ltures also became negative during treatment. Full etails of the progress of case I are given in the ccompanying figure, which illustrates the response to hloramphenicol of a treated case which relapsed.

PROGRESS OF CONTROLS

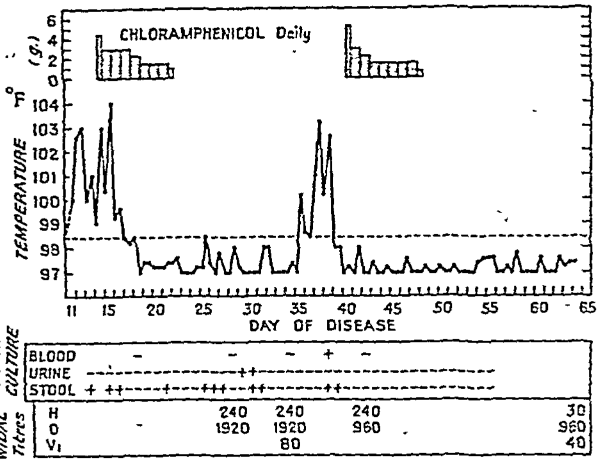
These 7 patients fall into three groups:

1. Three mild cases (C, E, and M) all of whom made an uninterrupted recovery.
2. One severe case (B).
3. Three cases (F, K, and L) who relapsed and later were given chloramphenicol. These will be referred to later.

Of the patients in group 1 little need be said, as their progress as mild cases of typhoid fever was uneventful.

The severe case in group 2, on the other hand, had the well-developed symptoms of enteric fever. When admitted on the 14th day of the disease he looked extremely ill, being toxic and feverish, with abdominal tenderness. Gradually, however, his condition improved and by the 20th day his temperature was normal. His progress was slower than had been noted in the treated cases, his headache persisted longer, his toxic state was not so quickly relieved, and his appetite and general feeling of well-being did not return so quickly. Eventually, however, he made a complete recovery.

Positive stools had been obtained from all untreated cases on their admission to hospital and these remained consistently positive throughout the whole period in which the treated group of patients were receiving chloramphenicol. This may be contrasted with the state of the treated patients, 3 out of 6 of whom, as has been mentioned, showed a temporary clearance during the time they were undergoing treatment.



Treatment, temperature, and laboratory findings in case I, showing relapse on 35th day successfully treated with a second course of chloramphenicol, begun on 38th day.

Periods of treatment and retreatment are shown within brackets. F = fæcal; B = blood.

Relapses Treated.—The condition of 3 of the control cases (F, L, and K) deteriorated to such an extent that we did not feel justified in denying them the advantages of chloramphenicol treatment.

The first of these cases, L, who had a positive blood-culture on the 17th day of the disease, two days later showed the usual signs of a clinical relapse. Since he was in the control group, the administration of chloramphenicol was delayed for some days in the hope that his symptoms would subside. However, on the 23rd day, a further positive blood-culture having been obtained, and the patient's condition showing no signs of improvement, it was decided to give him a course of chloramphenicol, and a total of 18·25 g. was given in the next seven and a half days.

Within twelve hours of the start of treatment the temperature fell rapidly from 100° to 97°F and the patient developed some of the signs of shock, with cold clammy skin, collapse, &c., though his pulse remained satisfactory both in rate and volume. He then passed a large offensive loose stool, and shortly afterwards his temperature rose to 100·2°F ; it then gradually fell to normal by the 28th day, and his subsequent recovery was uneventful.

The worsening of this patient's condition soon after the start of treatment is very similar to that described by Murgatroyd (1949). This was the only one of our cases to show such a temporary deterioration.

Cases F and K, who had shown symptoms of relapse on the 20th and 33rd days, were both given a full course of chloramphenicol, the average total dose being 20 g. in eight days. Both responded well, and their further clinical progress was satisfactory.

PROGRESS OF "CARRIER" CASE D

In the original treated group was one patient, D, whose clinical response to chloramphenicol had been satisfactory but who had consistently produced positive stools during the whole time she was under treatment or observation. In view of the benefit we had noted in relapse cases with a second course of chloramphenicol, this patient was given a second course, starting on the 61st day of the disease, in the hope that it would render her stools negative.

Since she had quite recovered from the acute symptoms of the disease we felt we were justified in increasing the dose. She was therefore given a total of 26·25 g. spread over eleven and a half days. During this course she passed the only 2 stools that were negative out of the 72 cultured, and she was eventually discharged from hospital on the 83rd day of disease, still excreting *S. typhi* freely. On discharge, her Vi titre had risen to 1/80, and there seems to be every likelihood that she will become a chronic carrier.

It is worth noting that Rumball and Moore (1949), using even larger doses of chloramphenicol, failed to eliminate the typhoid bacillus from a chronic fæcal carrier, though they also reported a temporary clearing of the stools while the drug was being given.

SENSITIVITY OF *S. typhi* TO CHLORAMPHENICOL

The possibility that strains of *S. typhi* isolated from patients treated with chloramphenicol might show an increased resistance to the drug was investigated, through the kindness of Prof. Robert Cruickshank, in the Wright-Fleming Institute of Microbiology. Selected cultures obtained before, during, and after treatment were examined but no alteration was found in the susceptibility of the organisms to the drug.

TOXICITY

No toxic effects resulting from the drug were observed in any of the cases receiving chloramphenicol. Three patients reported "night terrors" during the course of treatment, but similar experiences occurred among some of the untreated cases. One patient said he had a constant noise in his ears "as if it were raining," while 2 others reported an indefinite rash, one on the ankle and the other on the thighs.

CLEARANCE TESTS

When this trial was originally planned, the numbe treated and untreated cases were to be about eq and if this arrangement had been maintained a r comparison between the rates of clearance in the groups might have been made. As the trial proceed however, changes were made because we did not justified in withholding the drug from the cont cases whose condition was deteriorating, or from treated cases which had relapsed. As a result th were now four groups instead of the two origin planned :

1. Original or early treated cases (A, D, G, H, I, and J).
2. Untreated cases (B, C, E, F, K, L, and M).
3. Late treated cases—i.e., treated only in relapse (F, and L).
4. Relapse cases receiving second course (I and J).

As the test of clearance we had decided to accep 6 consecutive negative stool and urine examination However, when the time came to assess the results thi arrangement proved unworkable, for several patient who had six or more consecutive negative stools an urines, and were therefore considered clear, later produce one or more positive specimens. In consequence, whe the patients eventually came to be discharged, we wer still in doubt regarding their state of clearance.

This uncertainty regarding clearance, together with the division of the original treated and untreated groups of patients into four small groups, three of which had received chloramphenicol at some time during their illness, made it inadvisable to try to assess the clearing action of the drug.

The general impression was that one course of the drug in the recommended dosage had no effect on the rate of clearance of the stools. On the other hand, the two cases I and J, which had relapsed and received a second course, responded by complete clearance of both stool and urine, and these remained negative for the remainder of the period of observation. This may indicate that a longer course of treatment, larger doses, or a routine second course might possibly accelerate the clearance.

Since their discharge from hospital all these patient have been under the observation of Dr. Norman Wood, of the Public Health Laboratory, Reading, who has kindly done further cultural examinations. The stools of "carrier" case D have been positive on each of the 21 occasions when they have been examined, but only one positive culture has been obtained from each of cases B (control) and H (treated). The stools of the remaining patients, both treated and controls, have been free from infection.

Agglutination Results

Several times during their illness, sera from all the patients were examined for H, O, and Vi agglutinins. No variation in these titres could be attributed to chloramphenicol treatment.

RELAPSES

Though the response of the treated patients to chloramphenicol was striking and clinically very satisfactory, it should be pointed out that 3 out of the 6 treated patients relapsed. against 3 of the 7 untreated controls. The relapses in the treated group developed later (average 35th day) than those in the controls (average 25th day). The frequency of relapses in cases treated with chloramphenicol has lately been commented on by others, notably by Smadel et al. (1949), who have shown that they seem to be prevented by giving larger doses and a longer course of treatment.

DISCUSSION

After studying the effect of chloramphenicol in 6 primary cases and 3 relapses in this outbreak we believe to be a most valuable drug, with properties in the atment of typhoid fever which are at present unique. Its beneficial effects in our cases were chiefly clinical. rhaps the most striking was its control over the tients' temperature, which fell to normal within venty-two hours in all the primary and relapsed ses treated. At the same time the drug relieved the rsistent headache, which is so distressing in the early ages of typhoid fever, and reduced the toxæmia; e patients felt better, their appetites returned, and eir abdominal discomfort was lessened. In fact, all e clinical symptoms noted in our patients were either duced or favourably influenced. Since neither hæmor-age nor perforation occurred in any of our cases we n offer no opinion on the efficacy of the drug in reventing these complications.

With regard to relapses, the effect of chloramphenicol as disappointing, since half of our treated cases eveloped relapse symptoms and in 2 of them these ere sufficiently serious to justify further treatment. lowever, the response to the second course proved so atisfactory that this may be an indication that longer ourses of treatment, larger doses, or a routine second ourse should be given to all primary cases. One course f chloramphenicol did not prevent the development of he carrier state, and a second larger and longer course vas ineffective in clearing this condition once it had leveloped.

Unfortunately from the bacteriological point of view hloramphenicol has not proved efficient, though there s evidence that it had some effect. This was seen in the learing of some of the stools and in the sterilisation of the blood-stream during the treatment period. The learing effect was only temporary; nevertheless, it gain holds out the hope that with some modification in dosage, in the light of further experience, wholly satisfactory results will be obtained.

SUMMARY AND CONCLUSIONS

A clinical trial in 13 cases of typhoid fever, alternate cases being given chloramphenicol, showed that this antibiotic has a specific clinical effect in the disease.

In the 6 treated cases, a total dosage of 19–22 g. of the drug, given in eight days, did not prevent relapses or the development of the carrier state.

The relapses in the treated cases occurred later than in the untreated controls.

In 3 of the treated cases fæcal excretion of *S. typhi* stopped temporarily during treatment but started again either before or at the end of the course.

There was no evidence that *S. typhi* developed an increased resistance to chloramphenicol.

No toxic effects of the drug were noted.

Our sincere thanks are due to Dr. W. H. Bradley and Dr. Ian Taylor, of the Ministry of Health, and to Dr. R. Lewthwaite and Dr. Stanley White, all of whom visited us several times and gave us freely of their experience and advice; and to Dr. A. Felix, F.R.S., for his kind help and guidance in the preparation of this paper. We would like to record our appreciation of the whole-hearted coöperation we received from the matron, Miss Stacey, and the staff of the Victoria Infectious Diseases Hospital. The laboratory investigations, entailing the examination of over 1000 specimens, were done by Mr. C. R. B. Frampton, senior technician, Public Health Laboratory, Winchester, whose careful work provided the foundation of this investigation. We are also grateful to Mr. E. Seymour, chief sanitary inspector for Winchester city, for his help with the chart.

TREATMENT OF TYPHOID FEVER WITH CHLORAMPHENICOL

ADAM L. K. RANKIN
M.D. Edin., D.P.H.
MEDICAL SUPERINTENDENT, SOUTH MIDDLESEX FEVER HOSPITAL, ISLEWORTH

A. S. GRIMBLE
M.B. Lond.
LATE REGISTRAR AT THE HOSPITAL

CHLORAMPHENICOL, isolated by Ehrlich et al. (1947), was first reported as effective in typhoid fever by Woodward et al. (1948). Their observations have been confirmed by workers in various parts of the world (Murgatroyd 1949, 1 case: Douglas 1949, 2 cases: Vakil 1949, 14 cases; Lomax 1949, 1 case; Foster and Condon 1949, 1 case; Shah 1949, 33 cases; Patel et al. 1949, 6 cases; Cook and Marmion 1949, 14 cases; Kiledjian 1949, 3 cases; El Ramli 1949, 17 cases). Musotto (1949) has recorded some 500 cases in a waterborne outbreak, of which all the severe ones were treated with chloramphenicol, but he gives no definite figures. Smadel (1950) has reported on 45 cases treated with chloramphenicol, with 1 death.

The 18 cases reported here were seen between May, 1949, and January, 1950; 10 came from Crowthorne, Berks (see Bradley 1949), and 8 were seen later by one of us (A. L. K. R.). Of the 10 patients from Crowthorne 4 were treated with chloramphenicol on admission and 4 more received the drug during a relapse; of the 8 seen later, 5 were treated with chloramphenicol on admission; so altogether 9 cases were treated for the primary attack and 4 for a relapse. The 9 patients who received no chloramphenicol may be regarded as controls.

It was originally intended to carry out a controlled trial with chloramphenicol, but it seemed unjustifiable to withhold the drug from the more severe cases with continuous pyrexia and toxæmia with prostration and/or delirium.

METHODS

Diagnosis.—Salmonella typhi was isolated from the blood and/or fæces and urine in every case.

Dosage.—The dosage of chloramphenicol (P. D. & Co.) adopted was similar to that used by Woodward et al. (1948) in typhoid fever in Malaya. They gave an adult an initial dose of 50 mg. per kg. of body-weight, followed by 3 g. daily until the patient became afebrile, after which a slightly lower dose was given for five days: the average total dosage was 19·1 g. per patient over an average of 8·1 days.

Owing to the shortage of chloramphenicol in May, 1949, it was impossible to give the drug for more than nine days to the Crowthorne patients, but this was not thought to be a long enough course, and 4 patients, of the later series, who were admitted in the last three months of the trial when chloramphenicol was more plentiful, received it for eighteen to twenty days.

Adults received 4 g. as an initial dose, followed by 3 g. in divided doses daily until the temperature fell to normal (average three days), then 1·5 g. daily for a week, and finally 1 g. daily for a week. In 5 cases the chloramphenicol was given two-hourly while the patient was febrile and then four-hourly. In another 5 cases it was given four-hourly until the pyrexia subsided and then six-hourly. In 3 cases it was given twelve-hourly. The daily dosage was the same, whatever the interval between doses.

Children under 10 years were given either a half or a third of the adult dosage.

Two-hourly administration was recommended by Ley et al. (1948), who, in volunteers, obtained peak blood-levels half an hour after the dose was given by mouth, and showed that chloramphenicol was rapidly excreted. Woodward et al. (1948), with the dosage mentioned above, obtained peak blood-levels of 80 μg. per ml. in twenty-four hours, after which the levels fell to 20 μg. per ml. by the fourth day of treatment and remained at that figure or lower until the end of treatment. In-vitro investigations by Smith et al. (1948) showed that *S. typhi* was inactivated by chloramphenicol concentrations of 0·25 μg. per ml. In the present small series the blood-levels, estimated by microbiological assay, rose more slowly to peak values, and therapeutic levels were maintained whatever the spacing of the doses. The inactivation or excretion of chloramphenicol seemed to be moderately rapid.

BLOOD-LEVELS

The blood-chloramphenicol levels achieved in 4 illustrative cases were as follows:

Primary Attack.—Boy, aged 3 years. Dosage: 1·25 g. on admission, followed by 0·25 g. four-hourly, then six-hourly from fifth day.

	Blood-level (μg./ml.)
1st day, 1/4 hr. after dose	10

CLINICAL RESULTS

Crowthorne Patients (10)

Of the 4 patients treated with chloramphenicol on admission, a man of 77 died within seventy-two hours, and 2 of the others relapsed—a child of 3 years and a woman of 75. The remaining patient, a woman, aged 29, received 26 g. of chloramphenicol in nine days recovered uneventfully.

Fatal Case.—A man, aged 77, with advanced cardiovascu disease from which he had been expected to die for two three months before he contracted typhoid fever. On admis he was in an advanced typhoid state, with a dry, furred, fissured tongue, urinary and fæcal incontinence, tremor, continuous low muttering delirium, sub tendinum, carphology, and bronchopneumonia. He 10·5 g. of chloramphenicol in the seventy-two hours he died.

It was obviously expecting too much of the drug t cure this patient, whose death was undoubtedly due the intercurrent condition and hastened by toxæmi This was the only death in the series of 18 cases.

Relapses.—A boy, aged 3 years, relapsed on the thirty day of disease, eleven days after completing a course of 11·25 g. of chloramphenicol in eight days. This was the only case among the relapses in which attempts at blood-culture failed.

A woman, aged 75, on admission, according to her own doctor, was "moribund, with great prostration and physical signs of bronchopneumonia as well as typhoid fever." She relapsed eleven days after completing a course of 24 g. of chloramphenicol in nine days. The relapse occurred on the twenty-first day in hospital (day of disease on admission unknown). In the relapse she was extremely ill and had acute retention of urine, *Bact. coli* cystitis necessitating bladder washouts twice a day, myocarditis, and bronchopneumonia (lung puncture gave a pure culture of *S. typhi*).

Of the 6 patients not given chloramphenicol on admission 2 men, aged 36 and 58, and a woman of 62 relapsed; a woman of 59 had a recrudescence followed by a relapse; and the 2 remaining patients, children aged 2 and 4 years, recovered uneventfully. All 4 relapses and the 1 recrudescence were treated with chloramphenicol. Two cases are worthy of comment.

Relapse.—A woman, aged 62, became so ill with peripheral failure that she was given intravenous glucose. She also had acute retention of urine and myocarditis. She received 24·25 g. of chloramphenicol in nine days. Her pyrexia subsided within three days of the start of treatment, and she recovered without further incident.

Recrudescence and Relapse.—A woman, aged 59, was admitted on what was supposed to be the sixth day of disease Lysis began on the twelfth day, but a recrudescence started on the fifteenth day (blood-culture positive). She received 25·25 g. of chloramphenicol in eight days, and her pyrexia subsided in three days. On the nineteenth day of disease the patient had a small intestinal hæmorrhage. Her relapse began on the thirty-second day of disease, ten days after the end of her course of chloramphenicol. She also became so ill with signs of peripheral failure during her relapse that intravenous glucose was required. On the sixty-ninth day of disease she developed bronchopneumonia and, later, a *Bact. coli* urinary infection.

Second Series (8)

Five of these patients were treated with chloramphenicol, with much the same course as the Crowthorne cases but the remaining 4 with a longer course. All the 8 patients recovered, but in the treated group there was 1 relapse, in a nurse of 19, and 1 case developed cardiovascular complications.

Relapse after 29 Days' Apyrexia.—A nurse, aged 19, was admitted on Jan. 10, the thirteenth day of disease, and immediately put on a course of chloramphenicol. She relapsed on Feb. 11 after receiving 37·5 g. of chloramphenicol in twenty days. *On admission her temperature was* 102·6°F, but the pyrexia completely subsided by the third day of treatment (see figure). After an apyrexial period of twenty-nine days she had a typical relapse. This was quite outside our previous experience, so chloramphenicol was not started again for three days, but blood-cultures made on three successive days grew *S. typhi.* Another course of chloramphenicol was therefore begun, and her pyrexia subsided in four days. Thereafter she made a smooth recovery.

Complications.—A man, aged 72, was found on admission to have asymptomatic diabetes. He received no chloramnicol on admission but seven days later his condition eriorated and there were signs of myocarditis. Chloramnicol was started immediately and his general condition n improved. Apart from thrombosis in his left leg he had other complication and made an excellent recovery.

COMMENTS

ol and Urine Cultures

In the cases from Crowthorne treated with chlorphenicol for eight or nine days *S. typhi* was isolated m the fæces and/or the urine both during and after course of chloramphenicol. In the 5 cases of the ond series treated for at least eighteen days (except the nurse during her relapse), *S. typhi* was not lated from the fæces and/or urine after completion the course.

ration of Fever after Start of Chloramphenicol

In the 8 cases treated with chloramphenicol on mission and the 6 cases treated for relapses the average ration of fever after the start of chloramphenicol erapy was three days. In the 5 cases not treated with loramphenicol ("controls") the average duration of ver was fourteen and a half days. In 4 cases of paraphoid-B fever in the hospital at the same time, not eated with chloramphenicol, the average duration of ver was twenty-one and a half days.

fects of Chloramphenicol on Typhoid Fever

Except in the man of 77 who died of cardiovascular sease, the effects of chloramphenicol were exactly as scribed by Smadel (1950). The chief effects were on e temperature, which quickly fell to normal, and on e toxæmia, which was dispelled less rapidly but ually effectively. In no case did fever persist for more an four days after the start of chloramphenicol therapy. melioration in the patients' general condition was ually not noticeable for thirty-six to forty-eight hours, it between forty-eight and seventy-two hours the nprovement was very noticeable and in some cases amatic.

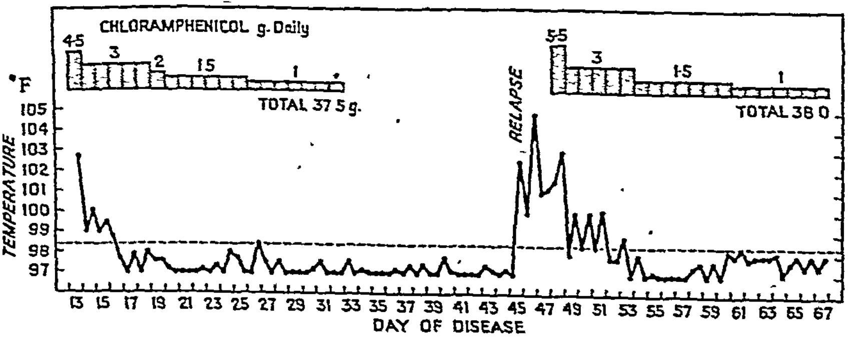
Chloramphenicol not only shortens the duration of the lness but also saves life. In this small series the woman 75 was undoubtedly saved by chloramphenicol, robably also the 2 women, aged 59 and 62, who had rdiovascular failure, and possibly the man of 72 who ad intercurrent diabetes and myocarditis.

oxic Reactions

No toxic or side-effects were observed in any of the atients who received chloramphenicol. The blood of ll the patients was examined at regular intervals. The lotting-time was reduced in the cases which were very l at the time of the estimation.

acterial Sensitivity

The chloramphenicol sensitivity of the strains of . *typhi* isolated before and after treatment, and after elapse and treatment, was investigated. No diminution n sensitivity of the organisms to chloramphenicol was bserved at any stage.



Dosage and temperature in a girl of 19, who relapsed after 29 days' apyrexia.

Complications

Woodward et al. (1948) showed that chloramphenicol does not prevent intestinal hæmorrhage and perforation, even when the patient becomes afebrile. The complications noted in this series were:

Sex	*Age*	*Acute retention of urine*	*Myocarditis*	*Bronchopneumonia*	*Cardiovascular failure*	*Intestinal hæmorrhage*	*Thrombosis of leg*	*B. coli urinary infection*
Female ..	75	+	+	+	0	0	0	+

PROGNOSIS IN ELDERLY PATIENTS

It is generally agreed that as age advances the chances of recovery from typhoid become less. Goodall (1928) found that the case-fatality ranged from 7·2% in the younger patients to 31·7% in the older ones. Rolleston and Ronaldson (1940) noted that the lowest case-fatality is between 5 and 10 years of age; it then increases, with each quinquennium to 40% at the age of 60 and onwards. Of 11,509 patients with typhoid fever admitted to the Metropolitan Asylums Board hospitals in 1899–1913, there were 53 between the ages of 55 and 60, of whom 17 died, a fatality-rate of 32%, and 30 patients aged 60 years and upwards, of whom 12 died, a fatality-rate of 40%. Harries and Mitman (1947) say that the fatality-rate is highest in children under 3 years and in adults of 60 years and upwards; in these groups it may reach 50%. Banks (1949) agrees that in patients over 40 the prognosis is poor and that in those over 60 the fatality-rate may be 50%.

In the present, admittedly small, series of 18 cases, 6 patients were over 58. Apart from the one death, in the man of 77 who was admitted in a hopeless condition, all the patients recovered. In our view, chloramphenicol saved the lives of some if not all of these elderly patients.

RELAPSES

Relapses in typhoid fever treated with chloramphenicol have been mentioned by several observers. In this series of 17 cases (excluding the fatal case) there were 8 relapses (47%). Of the 9 cases treated with chloramphenicol, 4 relapsed (44%), whereas among the 8 cases not treated with the drug there were 4 relapses (50%). The incidences are therefore about the same with and without the drug.

Curschmann (1923) found that the frequency of relapses varied in different epidemics from 1·4 to 17%. Goodall (1928) reported 347 relapses in 2947 cases treated in the Metropolitan Asylums Board hospitals 1892–1914—an incidence of 11·7%. Rolleston and Ronaldson (1940) noted that, in the whole period 1900–09, 10·4% of the cases of enteric fever admitted to the Metropolitan Asylums Board hospitals developed relapses, the annual frequency ranging from 8·6% in 1906 to 12·4% in 1903. Ker (1920) reported an incidence of 5·5% in 1700 cases treated at the Edinburgh City Fever Hospital, but he observed that the tendency to relapse was higher in some outbreaks, and for one year the incidence was 13%. Banks (1949) states that relapses occur in about 12% of cases.

In the present series, with the exception of the boy of 3 years in whom no positive blood-cultures were obtained, the nurse of 19 who relapsed after twenty-nine days' apyrexia, and a girl aged 5, the relapses occurred in the older patients.

Smadel et al. (1949) analysed their results in 44 cases treated with chloramphenicol and noted a striking relation between the duration of the course and the incidence of relapse. Relapses occurred in 7 out of 13 patients whose initial course of drug was given for eight days or less (average 6·9 days) and the total dose of chloramphenicol averaged 20 g. There were no relapses in a second group of 19 patients in whom the chloramphenicol was continued for nine to fourteen days (average 11·2 days) and the total dose averaged 25·7 g. A third group of 12 patients treated for fourteen to twenty-three days (average 18), the average total dose being 32·8 g., also had no relapses. All the relapses in their patients responded satisfactorily to chloramphenicol. They recommend a course of more than eight days for patients actually ill with typhoid fever, if relapses are to be avoided, but in their opinion little advantage is gained by continuing the treatment for more than fourteen days.

Recently Smadel (1950) mentioned that Woodward, the clinician of the American group, is using interrupted treatment in typhoid somewhat similar to that used to prevent relapses in the volunteers with scrub-typhus. The first five days of this régime are similar to the course mentioned; the drug is then omitted for five days, after which the original course is repeated. Woodward had no relapses in the 8 cases given this treatment.

CONCLUSIONS

No firm conclusions can be drawn from this small series, but the results suggest that chloramphenicol will be effective if given in adequate dosage over a minimum period of eighteen to twenty days, an initial dose of 4 g. being followed by 3 g. daily until the patient is apyrexial, then 1·5 g. daily for a week, and 1 g. daily for the final week. Chloramphenicol has undoubtedly eased the heavy strain that typhoid fever imposes on the nurses—an important factor these days, especially in infectious diseases hospitals, where the nursing shortage is still unsolved. Nevertheless, in typhoid fever, the success of any treatment still largely depends on the nurses' proficiency, devotion, and vigilance.

We wish to thank Sir Alexander Fleming, F.R.S., and Prof. Robert Cruickshank for their valuable assistance and for carrying out sensitivity tests and estimations of blood-levels. We are also indebted to the bacteriologists and laboratory technicians of Ashford Hospital and the West Middlesex Hospital for the bacteriological, serological, and hæmatological reports; to Dr. R. Lewthwaite and Dr. W. H. Bradley of the Ministry of Health, who made this investigation possible and whose advice and cooperation have been invaluable; to Dr. Stanley White, of Parke, Davis & Co. for his generous supply of the drug when stocks were low; and to Dr. A. Felix, F.R.S., and Dr. E. S. Anderson, of the Central Enteric Reference Laboratory and Bureau, for typing the strains of *S. typhi* isolated and determining the Vi titres of the sera of recovered patients.

CHLORAMPHENICOL IN TYPHOID FEVER

A. H. El Ramli
DIRECTOR, ABBASSIA FEVER HOSPITAL, CAIRO

Since Woodward et al. (1948) demonstrated the favourable response of typhoid fever to chloramphenicol, their findings have been confirmed in reports from the U.S.A. and France, and in a few cases in the United Kingdom (Bradley 1949, Murgatroyd 1949, Cook 1949).

The results in 200 cases of typhoid fever treated with chloramphenicol at the Abbassia Fever Hospital are analysed here. The patients studied were those admitted to the hospital between May and December, 1949, in which the clinical diagnosis of typhoid fever was proved by the isolation of *Salmonella typhi* from the blood. It was not considered justifiable to leave some cases without chloramphenicol as controls, especially since in a previous series all of 20 uncomplicated cases had responded quickly and favourably to chloramphenicol. All the patients were kept in bed for at least fourteen days after their temperature had returned to normal, and most of them were kept in hospital for three weeks or more after the fall of temperature to see whether a relapse would occur.

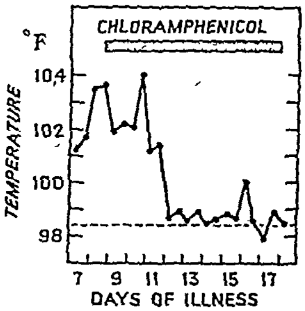

Fig. 1—Fall of temperature by crisis in a girl of 10 years.

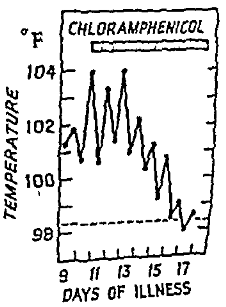

Fig. 2—Fall of temperature by lysis in a boy of 5 years.

The effect of chloramphenicol was assessed on (1) the behaviour of the temperature; (2) the incidence of relapses; (3) the occurrence of serious complications (hæmorrhage, perforation, &c.); and (4) the mortality. The response to chloramphenicol was studied in relation to: (1) the severity of the disease; (2) its duration

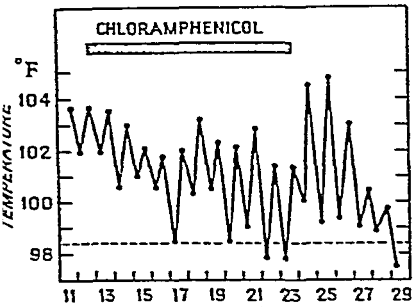
efore treatment: (3) the frequency of administration the drug; and (4) the patient's age and sex.

As regards dosage, the chloramphenicol was dispensed capsules containing 0·25 g. The dose given was about mg. per kg. of body-weight by month. This amount as then given daily until the temperature was normal; me patients received the same or a smaller dose for a ariable period up to fifteen days.

At the beginning of the study, chloramphenicol was iven two-hourly: later some of the patients had four-hourly, and the others twelve-hourly, doses. The responses to treatment of the different groups were then compared.



ig. 4—Resistance to chloramphenicol in a boy of 5 years.

RESULTS

Pyrexia

The temperature chart is our main objective guide to the patient's response to treatment. In nearly all cases defervescence occurred rapidly, and the temperature became normal after an average of 3·5 (S.E. 0·03) days (table I). In 7 very severe cases (3·5%), however, the temperature did not settle so quickly but remained high for 8–27 days. In most cases the temperature started to fall within the first day or two of the start of treatment, with corresponding symptomatic improvement. Figs. 1–5 show some of the ways in which defervescence took place after the administration of chloramphenicol.

Tables I and II show that there was no significant difference in the average duration of fever after treatment started, whether the patient was in the first, second, or third week of his illness or even later; whatever the severity of his condition; and whether he was given the drug two-hourly, four-hourly, or twelve-hourly. There was also no significant difference in the response of the fever in the two sexes.

TABLE I—EFFECT OF SEVERITY OF ILLNESS AND DURATION OF SYMPTOMS BEFORE TREATMENT ON RESPONSE

Days of symptoms before treatment	Severity of illness	No. of cases	Av. days of pyrexia after start of treatment	No. relapsed (% of cases followed for 3 weeks)	No. died
1–7	Moderate	5	2·6	..	..
	Severe	6	4·2	1	..
	Very severe	6	3·7	1	..
	All cases	17	3·5	2 (*16·7%*)	Nil
8–14	Moderate	28	3·0	2	..
	Severe	28	3·0	6	..
	Very severe	55	3·6	14	5
	All cases	112	3·3	22 (*25·5%*)	5 (*4·5%*)
15–21	Moderate	6	3·5	..	..
	Severe	7	3·6	..	..
	Very severe	31	3·9	11	4
	All cases	44	3·6	11 (*31·4%*)	4 (*9%*)
More than 21	Moderate	..	..	..	..
	Severe	3	4·3	1	..
	Very severe	24	3·8	5	4
	All cases	27	3·8	6 (*37·5%*)	4 (*15%*)
Grand total		200	3·5	41 (*27·5%*)	13 (*6·5%*)

Percentages are of cases observed for at least 3 weeks.

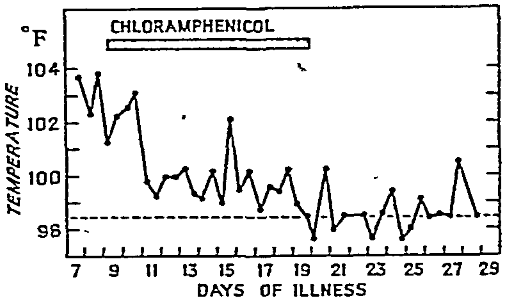


Fig. 5—Irregular temperature in convalescence in a man of 25.

Relapses

The relapse-rate was studied in the cases observed in hospital for three weeks or more after the temperature became normal. Some interesting conclusions can be drawn from the data in tables I–IV.

Table I shows that 27·5% of these cases relapsed. The relapse occurred after an average apyrexial period of 15·5 (S.E. 1·2) days, with a range of 6–31 days. It will be seen that the relapse-rates in cases treated during the first, second, or third week of their illness or later were 16·7, 25·5, 31·4, and 37·5% respectively. The difference between these rates is not statistically significant.

TABLE II—EFFECT OF FREQUENCY OF DOSES ON DURATION OF PYREXIA AND NUMBER OF RELAPSES

Frequency of doses	No. of cases treated	Av. days of pyrexia* after start of treatment	Severity	Relapses in cases observed for 3 weeks
Two-hourly	109	3·5	Moderate	0
			Severe	7 (*39·4%*)
			Very severe	19
Four-hourly	52	3·1	Moderate	0
			Severe	3 (*22·7%*)
			Very severe	7
Twelve-hourly	39	3·9	Moderate	0
			Severe	0 (*13·8%*)
			Very severe	4

* This was found to be independent of the severity of the illness.

Table II shows that when the same daily dose was given two-hourly, four-hourly, or twelve-hourly, the relapse-rates were 39·4, 22·7, and 13·8% respectively—i.e., the less often chloramphenical was given, the less was the probability of a relapse. The differences between 13·8% and each of 22·7% and 39·4% are statistically significant.

Table III shows that the relapse-rates were 26·7, 33·3, and 7·7% in groups of cases in which the drug was continued for up to five, ten, and fifteen days respectively into convalescence. The differences between 7·7% and each of 26·7% and 33·3% are statistically significant.

Table IV gives the relapse-rates in age-groups; there is no significant difference between these rates.

If the temperature in convalescence is irregular (this occurs in 21·5% of the cases), it does not follow that a relapse is more likely than if the temperature is normal and regular. Of the relapsed cases in the present series, 77% had a normal and regular temperature in convalescence and only 23% had intermittent pyrexia.

Serious Complications

Intestinal hæmorrhage occurred in 6 cases. In 3 of these it occurred on the second, fourth, and seventh days of treatment, and they all recovered. The other 3 patients had severe and repeated bleeding before and during treatment and all died of the hæmorrhage plus other complications (toxæmia, heart-failure, &c.).

twenty-nine days' apyrexia, and a girl aged 5, the relapses occurred in the older patients.

Smadel et al. (1949) analysed their results in 44 cases treated with chloramphenicol and noted a striking relation between the duration of the course and the incidence of relapse. Relapses occurred in 7 out of 13 patients whose initial course of drug was given for eight days or less (average 6·9 days) and the total dose of chloramphenicol averaged 20 g. There were no relapses in a second group of 19 patients in whom the chloramphenicol was continued for nine to fourteen days (average 11·2 days) and the total dose averaged 25·7 g. A third group of 12 patients treated for fourteen to twenty-three days (average 18), the average total dose being 32·8 g., also had no relapses. All the relapses in their patients responded satisfactorily to chloramphenicol. They recommend a course of more than eight days for patients actually ill with typhoid fever, if relapses are to be avoided, but in their opinion little advantage is gained by continuing the treatment for more than fourteen days.

Recently Smadel (1950) mentioned that Woodward, the clinician of the American group, is using interrupted treatment in typhoid somewhat similar to that used to prevent relapses in the volunteers with scrub-typhus. The first five days of this régime are similar to the course mentioned; the drug is then omitted for five days, after which the original course is repeated. Woodward had no relapses in the 8 cases given this treatment.

CONCLUSIONS

No firm conclusions can be drawn from this small series, but the results suggest that chloramphenicol will be effective if given in adequate dosage over a minimum period of eighteen to twenty days, an initial dose of 4 g. being followed by 3 g. daily until the patient is apyrexial, then 1·5 g. daily for a week, and 1 g. daily for the final week. Chloramphenicol has undoubtedly eased the heavy strain that typhoid fever imposes on the nurses—an important factor these days, especially in infectious diseases hospitals, where the nursing shortage is still unsolved. Nevertheless, in typhoid fever, the success of any treatment still largely depends on the nurses' proficiency, devotion, and vigilance.

. I—Diagrammatic representation of the principle of the repair: *a*, the normal arrangement, with the femoral ring closed by the emoral septum, a specialised part of the fascia transversalis; *b*, the femoral peritoneal sac is covered by the femoral septum; *c*, the ernial sac, with all its coverings, including the femoral septum, is reduced and excised; *d*, the lower leaf of the divided fascia transversalis s sutured to Astley Cooper's ligament; *e*, the posterior wall of the inguinal canal is reconstructed; *f*, the external oblique aponeurosis s overlapped, and the normal anatomical arrangement largely restored.

The new septum is as strong as the original and ossesses its elasticity. None of the structures forming e femoral canal or ring are displaced under tension, hich would impair their function and those of intimately lated structures. The posterior wall of the inguinal nal is restored to its normal strength and can be rengthened if need be, so preventing a direct inguinal ernia, a complication admittedly less serious than a moral recurrence, but one equally as annoying to the atient.

TECHNIQUE

A linear incision 10 cm. long is made starting just edial to the pubic tubercle and extending laterally 1 cm. oove and parallel to the inguinal ligament. The external blique aponeurosis is exposed. The deep layer of the perficial fascia is incised along its attachment to the edial portion of the inguinal ligament and fascia lata, nd the hernial sac is displayed. This is separated from he neighbouring structures, and the neck of the sac is lentified as it lies etween the inguinal igament anteriorly, the ectineus fascia posteriorly, Gimbernat's igament medially, and he femoral vein laterilly.

In the absence of trangulation the neck of the sac is detached rom the boundaries of the femoral ring by blunt dissection. Since this manœuvre often leads to reduction of a loop of bowel into the peritoneal cavity it is inadvisable when strangulation is present; in such circumstances the sac is opened and the bowel inspected before the neck of the sac is freed.

The aponeurosis of the external oblique is incised in the direction of its fibres; the cord is separated from the posterior wall of the inguinal canal, and the fascia transversalis displayed. An incision is made in the fascia transversalis at the junction of its upper two-thirds and lower third and carried laterally towards, but not so far as, the inferior epigastric artery. The hernial sac is withdrawn through the femoral ring, opened, ligatured, and excised. A swab is inserted into the extraperitoneal tissues, and the peritoneum is retracted medially to display the femoral ring from above.

Three silk sutures, no. 2, threaded on a no. 5 Ogilvie needle, are passed through Astley Cooper's ligament and the edge of the lower flap of the fascia transversalis, which in this part is reinforced by the deep femoral arch and iliopubic band (fig. 2). When these sutures are tied, the fascial flap rotates and, without tension, completely closes the femoral ring.

The posterior wall of the inguinal canal is reconstructed by suturing the upper flap of the fascia transversalis to the inguinal ligament at its junction with the lower flap of the fascia transversalis.

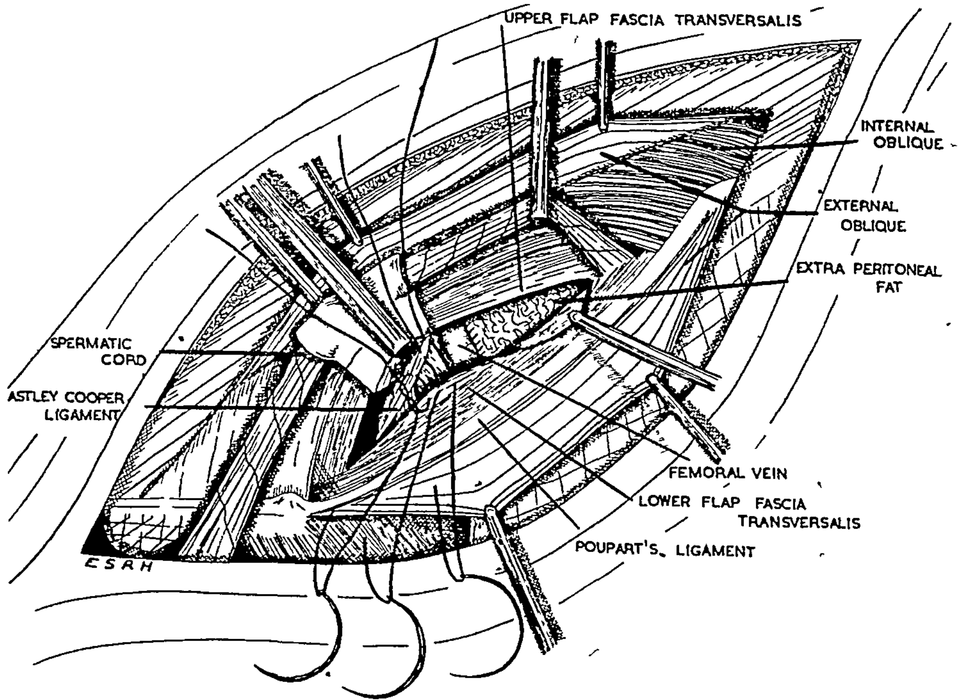

Fig. 2—No. 2 silk sutures threaded on no. 5 Ogilvie needles are passed through Astley Cooper's ligament and the edge of the lower flap of the fascia transversalis.

TABLE III—EFFECT OF DURATION OF TREATMENT IN CONVALESCENCE ON INCIDENCE OF RELAPSE

Days of treatment in convalescence	No. of cases	No. relapsed
0–5	75	20 (*26·7%*)
6–10	45	15 (*33·3%*)
11–15	26	2 (*7·7%*)

TABLE IV—RELAPSE-RATE IN AGE-GROUPS

Age (yr.)	0–5	6–10	11–20	21–30	Over 30
No. of cases ..	57	27	40	19	9
Relapses (%) ..	26·3	33·3	20	31·6	22·6

Perforation occurred in 7 cases (3·5%) and 2 of the patients died, including one who perforated three days after the start of chloramphenicol. Of the 5 who recovered, 3 were operated on not later than twelve hours after the perforation had been diagnosed; the other 2 recovered without operation. All the 5 cases had intensive chemotherapy with chloramphenicol, penicillin, and streptomycin.

Encephalitis developed in 4 cases, of which 1 was fatal.

Hæmorrhagic Type.—The series included 6 cases of the hæmorrhagic type; 5 of these patients died during chloramphenicol therapy, and one, a boy, recovered after 27 days' treatment with chloramphenicol.

Mortality

Of the 200 patients in this series, 13 died (6·5%), whereas the *mortality-rate* over the past ten years in our hospital was 9–12%. It should be noted, however, that 4 of the perforated cases, all the 6 with the hæmorrhagic type of disease, and 3 of those who had intestinal hæmorrhages were referred to me for chloramphenicol treatment and would not otherwise have come to the hospital. This accounts for the rather high mortality.

Toxic Effects

Contrary to the reports of other workers, I believe that the chloramphenicol was responsible for the following symptoms, because they were observed only in patients receiving this drug: anorexia, nausea and vomiting, stomatitis with glazed and sore tongue, rash (especially where sweating was severe), and mental apathy, was severe in some cases.

COMMENTS

Dosage

For the present it seems that the best scheme of dosage is 50 mg. per kg. of body-weight over the first two hours, and then 25 mg. per kg. every twelve hours until the temperature becomes normal and half that dose for fourteen days in convalescence. Rest in bed and symptomatic treatment should continue, as before chloramphenicol therapy, for at least another week.

Future Investigations

From the results in this series and a previous one, I am convinced that chloramphenicol provides the most efficient specific treatment for typhoid fever so far devised. I must emphasise the importance of nursing, symptomatic treatment, and rest in bed for at least three weeks after the subsidence of fever, for the toxic effects of the infection last longer than the pyrexia.

Work is now proceeding along two main lines:

(1) To find out the smallest effective dose of chloramphenicol, since there is evidence that half the dose used in this series—i.e., 25 instead of 50 mg. per kg. of body-weight daily—may give the same therapeutic response. Also it is important to estimate how long chloramphenicol therapy should be maintained after defervescence.

(2) In another series of cases the combined effect of chloramphenicol and sulphadiazine is being studied according to the recommendation of El Borolossy and Buttle (1949).

SUMMARY

A series of 200 cases of typhoid fever have been treated with chloramphenicol and the results analysed.

The average duration of fever after treatment started was 3·5 days, the relapse-rate in patients followed up for at least three weeks was 27·5%, and the mortality was 6·5%. Relapses were fewest on twelve-hourly doses.

The response to chloramphenicol was little affected by the severity of the condition or duration of symptoms before treatment.

Mild toxic effects, ascribed to chloramphenicol, were observed, including anorexia and gastric upsets, stomatitis and glossitis, rash, and apathy.

I am very grateful to my colleagues, Dr. A. Hamid Omar and Dr. A. W. El Borolossy, for their enthusiastic efforts in this work and in the preparation of this paper.

AN aim in the repair of any structural defect is a restoration to normal, but this can *only* be ideal if, at the same time, it prevents the recurrence of that defect.

The femoral ring seems to be composed of relatively immovable structures: Poupart's ligament anteriorly, Astley Cooper's ligament posteriorly, Gimbernat's ligament medially, and the femoral vein laterally. This potential defect is closed by the femoral septum, a specialised portion of the fascia transversalis, which does not form a rigid barrier, as can be proved at laparotomy by placing a finger on the abdominal aspect of the femoral canal.

In the repair described here the place of the femoral septum is taken not by rigid scar tissue but by the fascia transversalis which forms the inferior part of the posterior wall of the inguinal canal (fig. 1). The fascia transversalis is composed of two layers and is strengthened by certain bands. The superficial layer is continuous with the conjoint tendon and may be regarded as a continuation of the sheath covering the anterior and posterior surfaces of the conjoint muscles. The deep layer is the true fascia transversalis. The deep femoral arch is a strong band which blends below with the inguinal ligament and strengthens the lower third of the posterior wall of the inguinal canal; medially it is attached to the *ilio-inguinal* line, and laterally it disappears under the internal oblique muscle. The cremaster muscle arises from its anterior surface, and the transversalis fascia passes deep to its posterior surface to fuse with the femoral septum medially and the anterior wall of the femoral sheath laterally. The iliopubic band lies directly behind the deep femoral arch and stretches between the iliopectineal line and the anterior superior iliac spine. Henle's ligament and the interfoveolar ligament strengthen the medial and lateral portions of the fascia transversalis.

Œstrogen Therapy in Gynæcology

THE section of obstetrics and gynæcology met on March 17, under the chairmanship of Mr. A. J. McNAIR, to discuss the use of œstrogen therapy in gynæcology and obstetrics.

Prof. RAYMOND BOURG (Brussels) described his laboratory experiments on the effects of administering œstrogen to rats. In general the size of the dose determined the extent of ovarian secretion; but with larger doses the secretion of follicular hormone became relatively larger than that of luteal hormone. Clinically he had found that large doses gave the best results. Large doses injected over a short time had not yet been used clinically, but in amenorrhœa this method might sometimes prove very useful. Finally, Professor Bourg emphasised the importance, as an aid to clinical treatment, of experiments of the kind he had undertaken.

Dr. ARTHUR SUTHERLAND discussed functional uterine bleeding or, as some preferred to call it, dysfunctional uterine bleeding—a term usually applied to abnormal uterine bleeding without any obvious lesion.

Analysing 1000 cases of abnormal uterine bleeding occurring in the absence of gross pelvic abnormalities, Dr. Sutherland said that organic pathological lesions of the endometrium were present in 139 (chronic endometritis in 110, uterine polypi in 11, tuberculosis in 10, and malignant disease in 8). Among the remaining 861 patients endometrial hyperplasia was present in 265: irregular ripening of the endometrium in 26: and irregular shedding in 13; and endometrial atrophy in 10. In 547 the endometrium appeared normal. Although these 861 cases could be regarded as functional, in some instances this might not be so. The possibility of a pelvic cause not apparent on clinical examination must not be forgotten.

Œstrogen therapy was of relatively recent origin. From the present and other series it was evident that the incidence of endometrial hyperplasia was less than had been supposed, and that abnormal bleeding occurred from any type of endometrium. Œstrogen therapy was becoming increasingly popular. Karnaky used several œstrogens in varying doses; many of his cases were also given thyroid and Lugol's iodine, and it was not possible to state how far these contributed to the results. Some used a combination of one of the œstrogens and either progesterone or pregneninolone, administered cyclically. No conservative treatment of functional uterine bleeding produced better results than those obtained with œstrogen therapy.

Dr. Sutherland suggested that all cases of presumed functional bleeding should have a diagnostic curettage performed to eliminate unsuspected organic conditions; this should be done even for adolescent patients. A number were cured by the curettage, although the reason for this was not known. Patients who were not cured or greatly improved needed further treatment. For the large group of those at or near the menopause, hysterectomy or radiotherapy was preferable to endocrine treatment; and some severe cases in the late thirties occasionally required hysterectomy. Abnormal uterine bleeding in girls under 20 years of age was not common, and it could usually be cured by giving the antihæmorrhagic factor orally. In very young patients, where this failed, cyclic oral œstrogen therapy could be given. The efficacy of the antihæmorrhagic factor diminished with age, and Dr. Sutherland had almost abandoned using it for patients over 25. Other cases were usually treated with œstrogens.

Attention should be paid to the endometrial histology, and the alternative of androgen treatment should be considered in cases showing marked endometrial hyperplasia. Very occasionally patients showed no improvement and needed a further examination, including blood examination, estimation of prothrombin-time, urinary vitamin C, basal metabolic rate, and Wassermann reaction, and a further curettage. The possibility of emotional difficulties as a cause must be kept in mind, and when these were suspected the patient should be seen by a psychiatrist.

Mr. T. N. MACGREGOR said that abnormal uterine bleeding might be present in the first or second half of the menstrual cycle, or during the whole cycle. He described 38 cases of dysmenorrhœa, which had been under observation for from three months up to two years. The patients were aged 14–28, with an average age of 20, the average age of menarche being 13 years 4 months. Œstrogen was given during the first 20 days of the cycle. Sometimes the initial daily dose was not effective, and it had to be increased in subsequent cycles until ovulation was inhibited. When it was clear that ovulation had been suppressed, œstrogen was given daily from the 14th to the 24th day of each cycle. Œstrogen was not continued longer than 3 months if alleviation was not obtained. The drug relieved all cases where the dose was sufficient to suppress ovulation, but pain recurred at the next ovulation except in 14 cases which were apparently cured. In this series 55% were cured or relieved, 24% relapsed, and 22% derived no benefit.

Mr. MacGregor remarked that it was significant that no evidence of hyperplasia had been found. Probably the series included one or more patients with neurotic tendencies, yet œstrogen suppressed ovulation in all. This suggested that the pain was not psychosomatic but was due primarily to another cause, the psychological effect supervening as a result of recent pain.

The majority of women ovulated without pain, because the œstrogen and progesterone were in equilibrium. Imbalance was probably caused by over-production of progesterone rather than of œstrogen. Menstrual pain was due to hyperactivity of the uterine musculature, which could not be due to œstrogen; therefore, progesterone or an associated substance was probably the activating factor in uterine pain. It might be said that the activity of an organ, such as the uterus, which was under the control of the autonomic nervous system depended on a balance between the parasympathetic and the sympathetic systems. In this connection it was interesting that in the rabbit the administration of œstrogen had been shown to lead to the production of acetylcholine. It was possible, therefore, that œstrogens were parasympathetic stimulants. If this was correct, progesterone might have the opposite effect and act as a sympathetic stimulus. Œstrogen could only be of limited value, but sometimes it did help, and it should be considered before surgical treatment was decided on.

Prof. T. N. A. JEFFCOATE, dealing with the place of œstrogen therapy in pregnancy, remarked that early hopes in this regard had not been fulfilled. He believed that its value had been established beyond doubt only in the inhibition of lactation. It was less valuable in suppressing established lactation than in preventing its establishment. It was well known that in some animals all œstrogens caused abortion. In women they did not disturb a normal pregnancy or bring on early labour. It was not known whether they induced labour at term, yet women were regularly being given œstrogens in the hope of inducing labour. Professor Jeffcoate emphasised that it was no good giving œstrogen and expecting to see the result in a few hours; it took 12 hours to see the initial result, 24 hours to produce a reasonable

The operation is completed by overlapping the external oblique muscle anterior or posterior to the cord. If the sac is large, its removal leaves a space at the saphenous ring, which may be partially obliterated by approximating the superficial fascia to the fascia lata.

RESULTS

The method has been used in 31 cases; each patient has been followed for not less than two years. There have been no recurrences; and in no patient has an inguinal hernia developed.

SUMMARY

A repair which has been used in a series of femoral herniorraphies is described. The inferior portion of the fascia transversalis is turned downwards as a flap to form a new femoral septum.

AQUEOUS SUSPENSION OF PROCAINE PENICILLIN

Robert I. Cohen
M.B. Lpool, F.R.C.S.

SENIOR SURGICAL REGISTRAR, LIVERPOOL ROYAL INFIRMARY

A stable suspension of crystalline procaine penicillin in water should have the [illegible]eous solutions of penicillin with the [illegible] of procaine penicillin in oil. A short investigation has therefore been made with a new preparation of this type, 'Distaquaine.' There is no doubt about the clinical efficacy of penicillin in oil, but it is *troublesome to* administer because of its high viscosity, which necessitates a fairly large-bore needle, and a minor disadvantage is the difficulty experienced in cleaning the syringe after use. Moreover, some doctors do not look favourably on the intramuscular injection of an oily base.

The aqueous suspension supplied by the makers for this inquiry contains the stable crystalline procaine salt of penicillin G with less than 1·5 % of suspending agents. The suspended particles in the preparation are nearly all less than 40 μ in diameter; only an occasional particle reaches 60 μ. The potency is 1000 units per mg., which is the potency of pure procaine penicillin G.

METHOD OF ADMINISTRATION

Into a "single-dose" vial of aqueous suspension containing 330,000 units of penicillin 1·2 ml. of sterile water was injected and the vial was shaken. Next, as much as possible was withdrawn into the syringe. This amounted to about 1·5 ml., the increase being due to the solid crystals in suspension and also to some tiny air bubbles trapped in shaking the vial. No difficulty was encountered in giving the injection. Though 1·2 ml. of diluent makes a rather thick suspension, this was found to be much easier to give than the oily preparations previously tried. The suspension was made still easier to handle if 2 instead of 1·2 ml. of diluent was added, and this has since been the method of choice.

The injection was made into the triceps muscle at ordinary speed through a no. 14 needle. There is no need to hurry between mixing the diluent and injecting it, since even the diluted suspension is reasonably stable. A 2 ml. hypodermic syringe may be used. The syringe should be washed thoroughly after use, in water in the ordinary way.

FINDINGS

Thirty-two volunteers, chosen at random, were injected, 16 being kept in bed whereas the 16 others were ambulatory during the day of observation. No pain of any sort was complained of either early or *late*; several of the volunteers *did not know* they had had their injections. There was no swelling or redness, and no volunteer complained of stiffness.

Only *two* febrile reactions were noted, one of 99·2° and the *other* 99·8°F. Both settled within two hours.

The technique of assay was a modification of the serial-dilution method described by Randall et al.[2] *B. subtilis* was used, instead of *Staph. aureus*, as the test organism because of its greater sensitivity to a concentration of 0·012 unit per ml. But an end-point showing a level below 0·1 unit per ml. is difficult to interpret because of the natural inhibition of normal serum.

From the thirty-two volunteers given an intramuscular *injection of the* aqueous suspension of procaine penicillin, blood was taken at fixed intervals. Twenty-eight of the volunteers received 300,000 units, two received 600,000 units, and two were given 300,000 units repeated after twelve hours. The blood-penicillin levels are shown in the accompanying table. These figures compare with those published elsewhere[1] and for penicillin in oil[2]; further, except for three cases where the end-point of the assay was doubtful, the blood-level in all the volunteers was above the accepted effective minimum[3] of 0·03 unit per ml. up to 24 hours.

AVERAGE AND MAXIMUM AND MINIMUM BLOOD-PENICILLIN LEVELS 1–24 HR. AFTER INJECTION OF PENICILLIN G IN AQUEOUS SUSPENSION

No. of subjects	Dose (units)		Blood-penicillin levels (units per ml.)						
			1 hr.	2 hr.	4 hr.	8 hr.	12 hr.	18 hr.	24 hr.
12 (Amb.)	300,000	Av.	0·77	1·09	0·96	0·65	0·25	0·163	0·08
		Max.	1	2	2	1	0·5	0·25	0·125
		Min.	0·25	0·5	0·5	0·25	0·125	0·06	0·06
16 (Bed)	300,000	Av.	1·42	1·88	1·7	0·56	0·25	0·24	0·08
		Max.	2	4	4	1	0·5	0·25	0·125
		Min.	0·25	1	1	0·25	0·08	0·4	0·04
2 (Amb.)	600,000 (in two doses)	Av.	1	1	1	0·5	0·125	0·75	0·25
		Max.	1	1	1	0·5	0·125	1	0·25
		Min.	1	1	1	0·5	0·125	0·5	0·25
2 (Amb.)	600,000	Av.	2	2	2	1	0·5	0·18	0·1
		Max.	2	2	2	1	0·5	0·25	0·125
		Min.	2	2	2	*	0·5	0·125	0·08

* Contaminated. Amb. = ambulatory.

SUMMARY

In a trial of an aqueous suspension of penicillin G in adult volunteers intramuscular injection caused no difficulty or dilemma. A dilution to 2 ml. was easier to use than the recommended one to 1·2 ml.

No pain or discomfort was felt after the injections, but two subjects had a transient febrile reaction *without general upset.*

An effective blood-penicillin level of over 0·03 unit per ml. was maintained for twenty-four hours in 27 *out of 30 volunteers after a single intramuscular injection of 300,000 units.*

I am indebted to the Distillers Co. (Biochemicals) Ltd., for the hospitality of their laboratories and the help of their staff, particularly Mr. G. A. Glister. The aqueous suspension of procaine penicillin was supplied by that company.

Œstrogen Therapy in Gynæcology

THE section of obstetrics and gynæcology met on March 17, under the chairmanship of Mr. A. J. MCNAIR, to discuss the use of œstrogen therapy in gynæcology and obstetrics.

Prof. RAYMOND BOURG (Brussels) described his laboratory experiments on the effects of administering œstrogen to rats. In general the size of the dose determined the extent of ovarian secretion; but with larger doses the secretion of follicular hormone became relatively larger than that of luteal hormone. Clinically he had found that large doses gave the best results. Large doses injected over a short time had not yet been used clinically, but in amenorrhœa this method might sometimes prove very useful. Finally, Professor Bourg emphasised the importance, as an aid to clinical treatment, of experiments of the kind he had undertaken.

Dr. ARTHUR SUTHERLAND discussed functional uterine bleeding or, as some preferred to call it, dysfunctional uterine bleeding—a term usually applied to abnormal uterine bleeding without any obvious lesion.

Analysing 1000 cases of abnormal uterine bleeding occurring in the absence of gross pelvic abnormalities, Dr. Sutherland said that organic pathological lesions of the endometrium were present in 139 (chronic endometritis in 110, uterine polypi in 11, tuberculosis in 10, and malignant disease in 8). Among the remaining 861 patients endometrial hyperplasia was present in 265; irregular ripening of the endometrium in 26; and irregular shedding in 13; and endometrial atrophy in 10. In 547 the endometrium appeared normal. Although these 861 cases could be regarded as functional, in some instances this might not be so. The possibility of a pelvic cause not apparent on clinical examination must not be forgotten.

Œstrogen therapy was of relatively recent origin. From the present and other series it was evident that the incidence of endometrial hyperplasia was less than had been supposed, and that abnormal bleeding occurred from any type of endometrium. Œstrogen therapy was becoming increasingly popular. Karnaky used several œstrogens in varying doses: many of his cases were also given thyroid and Lugol's iodine, and it was not possible to state how far these contributed to the results. Some used a combination of one of the œstrogens and either progesterone or pregneninolone, administered cyclically. No conservative treatment of functional uterine bleeding produced better results than those obtained with œstrogen therapy.

Dr. Sutherland suggested that all cases of presumed functional bleeding should have a diagnostic curettage performed to eliminate unsuspected organic conditions: this should be done even for adolescent patients. A number were cured by the curettage, although the reason for this was not known. Patients who were not cured or greatly improved needed further treatment. For the large group of those at or near the menopause, hysterectomy or radiotherapy was preferable to endocrine treatment; and some severe cases in the late thirties occasionally required hysterectomy. Abnormal uterine bleeding in girls under 20 years of age was not common, and it could usually be cured by giving the antihæmorrhagic factor orally. In very young patients, where this failed, cyclic oral œstrogen therapy could be given. The efficacy of the antihæmorrhagic factor diminished with age, and Dr. Sutherland had almost abandoned using it for patients over 25. Other cases were usually treated with œstrogens.

Attention should be paid to the endometrial histology, and the alternative of androgen treatment should be considered in cases showing marked endometrial hyperplasia. Very occasionally patients showed no improvement and needed a further examination, including blood examination, estimation of prothrombin-time, urinary vitamin C, basal metabolic rate, and Wassermann reaction, and a further curettage. The possibility of emotional difficulties as a cause must be kept in mind, and when these were suspected the patient should be seen by a psychiatrist.

Mr. T. N. MACGREGOR said that abnormal uterine bleeding might be present in the first or second half of the menstrual cycle, or during the whole cycle. He described 38 cases of dysmenorrhœa, which had been under observation for from three months up to two years. The patients were aged 14–28, with an average age of 20, the average age of menarche being 13 years 4 months. Œstrogen was given during the first 20 days of the cycle. Sometimes the initial daily dose was not effective, and it had to be increased in subsequent cycles until ovulation was inhibited. When it was clear that ovulation had been suppressed, œstrogen was given daily from the 14th to the 24th day of each cycle. Œstrogen was not continued longer than 3 months if alleviation was not obtained. The drug relieved all cases where the dose was sufficient to suppress ovulation, but pain recurred at the next ovulation except in 14 cases which were apparently cured. In this series 55% were cured or relieved, 24% relapsed, and 22% derived no benefit.

Mr. MacGregor remarked that it was significant that no evidence of hyperplasia had been found. Probably the series included one or more patients with neurotic tendencies, yet œstrogen suppressed ovulation in all. This suggested that the pain was not psychosomatic but was due primarily to another cause, the psychological effect supervening as a result of recent pain.

The majority of women ovulated without pain, because the œstrogen and progesterone were in equilibrium. Imbalance was probably caused by over-production of progesterone rather than of œstrogen. Menstrual pain was due to hyperactivity of the uterine musculature, which could not be due to œstrogen; therefore, progesterone or an associated substance was probably the activating factor in uterine pain. It might be said that the activity of an organ, such as the uterus, which was under the control of the autonomic nervous system depended on a balance between the parasympathetic and the sympathetic systems. In this connection it was interesting that in the rabbit the administration of œstrogen had been shown to lead to the production of acetylcholine. It was possible, therefore, that œstrogens were parasympathetic stimulants. If this was correct, progesterone might have the opposite effect and act as a sympathetic stimulus. Œstrogen could only be of limited value, but sometimes it did help, and it should be considered before surgical treatment was decided on.

Prof. T. N. A. JEFFCOATE, dealing with the place of œstrogen therapy in pregnancy, remarked that early hopes in this regard had not been fulfilled. He believed that its value had been established beyond doubt only in the inhibition of lactation. It was less valuable in suppressing established lactation than in preventing its establishment. It was well known that in some animals all œstrogens caused abortion. In women they did not disturb a normal pregnancy or bring on early labour. It was not known whether they induced labour at term, yet women were regularly being given œstrogens in the hope of inducing labour. Professor Jeffcoate emphasised that it was no good giving œstrogen and expecting to see the result in a few hours; it took 12 hours to see the initial result, 24 hours to produce a reasonable effect, and 3–4 days to produce a maximum effect. It might be a week before any effect was evident.

On inertia, Professor Jeffcoate said that this had never been shown to be due to low œstrogen level in the blood. When inertia was the result of mechanical failure, œstrogen therapy rarely had any effect; nor did it help hypertonic inertia; but it seemed to have some effect on hypotonic inertia. The time was not ripe to deny that œstrogen therapy had any place in inertia.

The wheel had moved through a full circle; and œstrogen, which had been feared as the cause of abortion, was now used as a preventive. It stimulated expulsion where the fœtus was dead, and if given for 5–8 days would produce abortion in 80% of these cases. But Professor Jeffcoate sometimes wondered in how many of these cases the uterus would have evacuated itself in any event. It seemed important that someone should do a controlled experiment.

What of the use of œstrogens in pregnancy in diabetic women "and as a prophylactic against all the ills that may affect a woman in pregnancy"? There was a tendency to regard œstrogen therapy as acting not on the muscle so much as on the placenta and on the nutrition of the fœtus. This theory appeared a little too good to be true, but it might have something important to offer. It was important that large-scale controlled clinical experiments should be carried out on this. Some workers in Britain had failed to confirm the findings on which the theory was based.

Finally, Professor Jeffcoate posed the question: Why do synthetic or natural œstrogens, which in large doses produce vomiting or nausea in normal women, never cause this in the pregnant woman?

The Diagnosis of Diabetes Insipidus

At a meeting of the section of endocrinology on March 22, with Mr. L. R. BROSTER in the chair, a discussion on the diagnosis of diabetes insipidus was opened by Prof. J. H. BURN.

Professor Burn gave a short historical account of the use of nicotine as a stimulant of the antidiuretic function of the posterior pituitary. He cited the discovery of this action as a rare example of successful logical conjecture in pharmacology. Pickford had shown in 1939 that acetylcholine could inhibit diuresis in atropinised dogs. Thus the effect was attributed to the nicotine-like rather than the muscarine-like effect of acetylcholine, since the latter was neutralised by atropine. Therefore, nicotine itself was tried; and it also was found to inhibit diuresis in dogs, though it had no effect on hypophysectomised dogs. Further careful work, which involved injecting as little as 2 µg. of acetylcholine through the eye and following the path of such injections by indian ink, showed that the drug acted on the supraoptic nuclei.

Professor Burn then referred to his own work, which revealed close similarity in antidiuretic effect between nicotine or the smoking of one or two cigarettes on the one hand, and the injection of 50–100 milli-units of posterior pituitary extract on the other. He thought that the pressor and antidiuretic principles of the posterior pituitary were probably the same substance: and it was interesting that the same order of dose of posterior-pituitary extract which produced antidiuresis in dogs also caused a definite decrease in the coronary blood-flow of the dog heart-lung preparation. There was here a suggestion of the mechanism by which smoking might impair physical training.

Prof. R. KOURILSKY (Paris) reported the results of much work on a group of patients presenting with polyuria or polydipsia. He used a water-restriction test, sometimes with an additional salt load, and studied the urinary and blood changes. He classified his cases in three groups. Group I suffered progressive dehydration on water restriction. At necropsy these cases had complete destruction of the posterior lobe of the pituitary, but not of the anterior lobe or of the supraoptic nuclei. Group II first lost weight quickly on water deprivation, but then reached a stable state in which fluid intake and output balanced. The histological picture in one such case was of only partial destruction of the posterior pituitary—by a metastatic neoplasm in this instance. Group III presented with polydipsia, but without polyuria of parallel severity, the discrepancy in fluid balance being due to excessive fluid lost in sweating. These cases could concentrate the urine up to a specific gravity of 1·030 or more, whereas the maximum achieved by true diabetes-insipidus cases of group I was 1·010. In these cases added salt produced a greater increase of thirst than in normal subjects, and Professor Kourilsky attributed the defect in this third group to a specific lesion of the thirst-controlling mechanism rather than of the antidiuretic mechanism. Furthermore, his pathological studies had shown hypothalamic destruction without involvement of the posterior pituitary. In one case, in which a subarachnoid cyst was exerting pressure on the hypothalamus, puncture of the cyst produced immediate, dramatic relief of the abnormal thirst and polydipsia, and only later relief of the polyuria. These cases were resistant to the antidiuretic action of posterior-pituitary extracts.

Further evidence of a separate causation of true diabetes insipidus was derived from the observation that in cases of groups I and II, antidiuretic hormone started to relieve the polyuria before the polydipsia. The only experimental support for the presence of a separate thirst centre in the hypothalamus was produced by Hess, who could stimulate polydipsia in a cat by an electrode situated in the hypothalamus. This had not been confirmed. In man procaine block of the stellate ganglion might induce thirst, presumably by the effect on the salivary glands; and Professor Kourilsky suggested that such an autonomic block might prevent inhibition of thirst normally constantly maintained by a hypothalamic centre.

Professor Kourilsky said that normal men drinking excessive amounts of water up to 15 litres a day eventually developed a habit of thirst, which maintained their water intake at a high level. The polydipsia was usually associated with drowsiness and fatigue, which had been attributed to excessive flushing of sodium chloride out of the body. If the water intake was suddenly cut to normal, there was great thirst, anorexia, tiredness, and fretting, reminiscent of untreated diabetes insipidus. He concluded that thirst could be a habit which outlived its cause, whether this was originally organic or merely a voluntary polydipsia. The immediate response to both water load and deprivation tests might be masked by the body's water-reserve capacity, which varied from 500 to 3000 ml.; this reserve, which tended to be larger in women, was under hormonal control.

Dr. O. GARROD described his use, with Dr. J. E. CATES, of nicotine as a differential test for cases of polydipsia and polyuria. Their clinical material included 8 cases of diabetes insipidus and 2 of functional polydipsia, and 2 heavy smokers. Apart from the clinical characteristics of the cases, the diagnosis was based on the results of the following investigations:

1. Water deprivation for 20–24 hours, which caused the loss of up to 4 lb. in weight and a concentration of the urine to a specific gravity of up to only 1·014 in the diabetes-insipidus cases, but of over 1·020 in the functional ones.

2. A hypertonic-saline injection test for antidiuretic effect.

3. A test dose of 0·1 unit pitressin intravenously for antidiuretic effect.

4. A nicotine test. This started with six hours' water deprivation followed by large amounts of water orally to produce a good diuresis. At the height of the diuresis nicotine was given in a dose of 3 mg. (expressed as nicotine base) to smokers, and of 1 mg. to non-smokers, who were more susceptible. The urine was collected every 15 minutes from an indwelling catheter. The volume and chloride concentration were measured, as also was the creatinine output and blood-pressure in a number of cases.

These doses of nicotine failed to inhibit diuresis in 4 of the 6 patients with diabetes insipidus who smoked, and in the other 2 produced a transient antidiuretic effect and some increase in urinary sodium-chloride concentration. Of the 2 patients with diabetes insipidus who did not smoke, 1 gave an antidiuretic response to the 1 mg. dose of nicotine. When these doses of nicotine were doubled, there was a definitely greater antidiuretic response in the same subjects, but also a high incidence of side-effects such as dizziness, paræsthesiæ, hyperpnœa, palpitations, sense of constriction in the chest, blurring of vision, and occasional nausea and vomiting. In fact it was clear that cases of diabetes insipidus might have nicotine side-effects without an antidiuretic response, whereas in normals the antidiuretic effect was the one most easily produced. The blood-pressure and creatinine-clearance tests were used to assess the possible rôle of decreased glomerular filtration rate (G.F.R.) in producing an antidiuretic effect. In 1 case the G.F.R. did fall, but this could not be held to account for more than a small fraction of the total antidiuretic effect. Dr. Garrod concluded that in diabetes insipidus a sufficiently powerful nicotine stimulus could activate the supraoptico-hypophyseal pathway, showing that the lesions could only have been partial.

Dr. A. A. G. LEWIS, together with Dr. T. M. CHALMERS, described the employment of the nicotine test for diabetes insipidus. Preliminary work had confirmed the hypothesis of Burn and others that nicotine acted through the release of antidiuretic hormone from the posterior pituitary. By matching diuresis curves produced by nicotine with those obtained by graded doses of posterior-pituitary extract, it proved possible to calibrate the response to nicotine administered intravenously. The sodium-chloride concentration of the urine was also measured; although this increased during both types of diuresis, the total output changed very little, or sometimes decreased slightly after pitressin. The nicotine test was performed during diuresis produced by drinking 1 litre of water. The urine was then collected every 10 minutes. In each case the response was expressed in equivalent milli-units of pitressin by doing at least two tests with different doses of pitressin on each subject and constructing a dose-response curve. The logarithm of the dose of pitressin was found to bear a linear relation to the duration of inhibition of diuresis. The slope of the line indicated that doubling the dose produced about 10 minutes' longer antidiuretic effect. Calibrated diuretic curves were also constructed for the effect of smoking 1–3 cigarettes. Smoking one cigarette with full inhalation was found to be equivalent in effect to about 1·5 mg. of nicotine base; and after inhaling the smoke of three cigarettes in succession there was a much impaired antidiuretic response to pitressin injections.

Nicotine given intravenously was shown to be able to cause a pronounced drop in blood-pressure, associated in one case with syncope; and thus in such experiments the decreased G.F.R. must complicate the interpretation. On the basis of this nicotine test, Dr. Lewis divided his cases into two groups: in one the supraoptico-hypophyseal mechanism was destroyed, and in the other it could still be stimulated.

Reviews of Books

Annual Review of Microbiology

Vol. III. Editor: CHARLES E. CLIFTON. Stanford, California: Annual Reviews. 1949. Pp. 476. $6.00.

The Nature of the Bacterial Surface

Editors: A. A. MILES and N. W. PIRIE. Oxford: Blackwell Scientific Publications. 1949. Pp. 179. 15s.

IT is said that a condition of tenure of certain academic posts in the United States is the annual publication of one or more "papers." If this were true (which we doubt) it would explain those numerous essays on such subjects as the Blood Beryllium in 100 Cases of Hallux Rigidus which so often hinder the search for what we wish to read. Excessive publication is a worry affecting every branch of learning; and though nobody doubts that the preparation of minor original investigations for the press is invaluable training for the young, the practical results have been much weariness for all. Hence the development of some new forms of publication to allow "what matters" to receive attention.

Though the idea is by no means novel, the review of new knowledge published as an annual volume seems to be gaining fresh popularity. Typical of these is the *Annual Review of Microbiology*, and its third volume illustrates both the strength and weakness of this medium. The subject of microbiology is already divided into sections—of interest to the agronomist, the brewster, and the physician, among many others—and each section is by now barely comprehensible to students of the others. Thus a microbiological review, if it is to live up to its name, must include much matter which is of interest to only a minority of those who call themselves microbiologists. It would be foolish, also, to imagine that volumes of this kind are a substitute for hours spent in the library. Nevertheless they offer, at worst, a classified series of signposts which may save many fruitless hours; and when the reviewer has done his work properly he provides not a compilation but a synthesis, intelligible to those of us whose mild curiosity extends into fields outside our own. While no contributor to this volume exhibits the contemplative authority of a Burnet or an Andrewes, the level of contributions is high. Taliaferro on the cellular basis of immunity and Erikson on the actinomycetes seem outstanding, but it would be fair to say that to the average microbiologist, if such exists, half the book will be interesting and three-quarters understandable. The indices, both of authors quoted and of subjects, are excellent.

A second type of publication now making headway is the report of a conference. Those who were present at the symposium on the Nature of the Bacterial Surface, held by the Society for General Microbiology last April, are not likely to forget the feast of ideas set before what could accurately be called a delighted audience. In the account of the proceedings, those who spoke, not only as principals but in secondary parts and as interlocutors, have been given space and illustrations on a lavish scale, and praise is due not only to Dr. Miles and Mr. Pirie, who edit this volume, but to the anonymous stenographer whose record reads like *Hansard*. Most of the few hundred who do not regard such subjects as mere scientific trifling heard the disputations, and most will want this book; they will be surprised how vividly their memories are stirred.

We should add, perhaps, that success in this genre is not as easy as might be thought. The symposium-conference is expensive; the all-star cast is apt to be elusive; and the range of subjects which lend themselves to this form of discussion is limited. It is the essence of a symposium that those who take part must differ, not only in their conclusions but in their lines of approach; yet neither must be so diverse that understanding, and even some fusion of ideas, is impossible. (A colloquy between a flat-earthist and the Astronomer Royal might be entertaining, but it would not be a symposium.) At the same time, communications to scientific meetings so rarely evoke a constructive discussion at the time that committees of learned societies might well consider whether some of their time would not be better spent in planned debate. And if their results are as good as those of the microbiologists, they will be wise to publish them for the benefit of all.

Bedside Diagnosis

CHARLES MACKAY SEWARD, M.D., F.R.C.P.E., physician to the Royal Devon and Exeter Hospital. Edinburgh: E. & S. Livingstone. 1949. Pp. 372. 17*s.* 6*d.*

NEITHER "textbook" nor "handbook" quite fits this book; it is perhaps best described as a guidebook to diagnosis. It shows the reader his way about the diagnostic field, and does it very well. Dr. Seward's plan has been to choose the commonest and most significant of the main presenting symptoms and give to each a chapter (pain being regionally subdivided). For each he indicates its mechanism or physiology, lays down an appropriate "diagnostic approach," and lists the diseases likely to be responsible, describing their ætiology and main symptoms, and the examination and investigations necessary to identify or exclude them.

The choice of leading symptoms may seem a little arbitrary. It includes epistaxis, but not vertigo or any sensory or motor paresis; so diseases of the central nervous system receive scanty attention. Save that pain is rightly given precedence, the ordering of the chapters follows no very obvious plan, and it seems somewhat illogical to place the chapter on anæmia—a pathological state—between those on such unqualified symptoms as lateral abdominal pain and nose-bleeding. But these are small points. All the chapters are good in themselves and calculated to encourage careful history-taking and the use of eyes, ears, hands, the "scopes," and such tests as a competent doctor can and should make for himself. A sense of proportion pervades the book. Common disorders and those in which a wise patient would most desire early and accurate diagnosis are emphasised and put first; the more erudite investigations and tests are not forgotten but are never exalted above their worth. Simple and convincing clinical statistics and an occasional aphorism, judiciously chosen quotation, or personal experience reinforce the argument. The book should give a fresh slant on medicine to students reading for their finals, stimulate the imagination of young doctors beginning practice, or older ones who have got into grooves, and prove a useful consultant to anyone perplexed by a diagnostic problem.

Die Bazillenruhr

LUDWIG ROEMHELD, Dozent für Innere Medizin. Stuttgart: Thieme. 1949. Pp. 125. D.M. 10.80.

Dr. Roemheld has written a concise account of bacillary dysentery, mainly collected from epidemics occurring during the late war. From a very large material he has summarised the clinical and other findings, and, though little of the information will be fresh to specialists in this study, there is much to interest the general physician and student. The main chapters cover clinical manifestations, pathology, and treatment, and there is a large bibliography. It is noteworthy that in 1942 the case-mortality in Dr. Roemheld's series was as high as 2·3%. The main complications are very fully described, including the combination of urethritis, conjunctivitis, and arthritis known as Reiter's syndrome. The severe effect of dysentery on the circulation is rightly emphasised, and the importance of early treatment of all cases of diarrhœa, especially in the presence of an epidemic. Stress is laid on the dangers of using opium and the need for using sulphonamides early. The short chapter on prognosis—a difficult subject—is perhaps somewhat too condensed, but in general this account of dysentery will be welcomed as a useful summary of present knowledge.

Introduction to Public Health Law

JOHN J. CLARKE, M.A., F.S.S., of Gray's Inn and the Northern Circuit; barrister-at-law. London: Cleaver-Hume Press. 1949. Pp. 138. 12*s.* 6*d.*

MEDICAL graduates who take up public health as a career find it difficult, and generally boring, to digest the law relating to their duties. This little book will help them greatly, for it has three virtues—it is interesting, it is easily understandable by those who have had no legal training, and without being ponderous it contains all that is essential. Moreover it is well arranged. It deals with the legal enactments of the past hundred years since the great Public Health Act of 1848, but is mainly concerned with the four main Acts which govern present-day practice—the Public Health Act of 1936; the Food and Drugs Act of 1938; the Water Act of 1945, and the National Health Service Act of 1946. The appendix gives in chronological order the Public Health Acts passed from 1848 to 1948, and a short bibliography of reference books which medical officers of health may need to consult. Students for the D.P.H. will find in this book all that is essential for them to know, and senior medical officers will find it useful for clearing the confusion which results from having to administer changing Acts: it is not always easy to recall what is the law and distinguish it from what was the law.

Introduction to Clinical Perimetry (6th ed. London: Henry Kimpton. 1949. Pp. 332. 42*s.*).—The 6th edition of this work by Mr. H. M. Traquair, F.R.C.S.E., shows no major alterations, and indeed is so complete that none are possible. The visual pathways have been accurately traced from retina to occipital cortex; and, though the rare case may produce interesting findings, nothing can change the basic principles on which perimetry is founded, or alter the findings in a typical case. After some opening chapters on methods and apparatus, the author deals with the subject on an anatomical basis and gives examples of field defects due to disease or injury at all points of the visual nerve path. His book is accepted teaching in this and many other countries, and the standard is well maintained in the present edition.

Psychical Physics. *A Scientific Analysis of Dowsing, Radiesthesia and Kindred Divining Phenomena* (Amsterdam and London: Elsevir Publishing Co. 1949. Pp. 534. 60*s.*).—Prof. S. W. Tromp, the very industrious and candid author of this treatise, ranges far and wide in his search for evidence and explanation of water-divining. He gives his reasons for believing that there are created in and around living organisms and in the earth crust and the atmosphere electromagnetic fields, the interaction between which would account for the phenomenon of "divining." Some experiments of his own, conducted in laboratories in Holland, led him to conclude that a careful analysis of these and kindred happenings might prove to be of great value for medical research. Of this his book fails to persuade the medical reader, who—while cautiously mindful of Professor Rhine and extrasensory perception—takes a less favourable view than Professor Tromp of certain reports—e.g., about Dr. Boyd's emanometer and Dr. Abrams's box. Such a reader doubts whether "radiesthesia" (divination by pendulums) can be of use in diagnosis and treatment, and is content to remain a sceptic so long as the data about divining and its necessary conditions and relevance to medicine are in the state which the reports here assembled disclose.

Physiology of the Uterus (2nd ed. London: Cassell. 1949. Pp. 611. 93*s.*).—In this work Mr. S. R. M. Reynolds, PH.D., a lecturer at Johns Hopkins University, supplies a connected account of what is known of the physiology of the uterine muscle. It is ten years since the appearance of the first edition, and in spite of the dislocation of research entailed by the war, much new material is available and needs assessing. There is no similar volume on this subject; it stands alone, and is wonderfully thorough. This edition is arranged differently from the first. The book is now divided into eight sections devoted to such subjects as uterine growth, functions and hormone control of the myometrium and uterine contractions, the circulation, metabolism and innervation of the uterus, and the onset of labour. In spite of the huge number of the original articles he has collected and consulted, Dr. Reynolds has produced a readable book of great interest to physiologists and to those who try to base their clinical work or clinical teaching on physiology. The whole is beautifully edited and presented, and contains some 70 illustrations. Dr. Reynolds has undertaken a task which will never be completed, and which will never allow him to rest. It was time someone accepted this heavy duty, for the gaps are perhaps larger in our knowledge of this branch of physiology than in any other. Doubtless this book has already stimulated much research.

THE LANCET

LONDON: SATURDAY, APRIL 1, 1950

The New Medical Bill

In 1942 the Medical Planning Commission, appointed by the British Medical Association, said that "it would be an advantage to both the community and the practitioner if, when the medical student has passed his final examination, he could spend some time in practice under supervision before he embarked in practice on his own account." This opinion was endorsed by the General Medical Council in 1943, and elaborated by the Goodenough Committee, which in 1944 recommended that "every student, after he has passed his final qualifying examination and before he is admitted to the Medical Register and allowed to enter independent medical practice, should be required to serve as a junior house-officer for a period of twelve months in one or more approved hospitals." The Goodenough Committee considered the proposal that part of the twelve months should be spent outside hospital, in some other form of approved practice—e.g., as assistant in a laboratory or a health centre, or as apprentice to a general practitioner—but felt that in present circumstances the student would benefit most by spending the whole time in hospital, preferably devoting six months to a medical post and six months to a surgical one. The responsibility for finding him suitable posts was to rest on his teaching school, and, though the duties he would perform would approximate to those assigned in teaching hospitals to newly qualified house-officers, his status as a student still needing guidance and supervision was to be marked by giving him the care of fewer beds, with correspondingly more time for thought and study. The committee had in mind a maximum of 20 beds in teaching hospitals, and 30 beds in others, but thought that at first, in order to provide enough appointments, the figures might have to be 15 and 25.

Before the war only about half the doctors qualifying in this country took house-appointments before leaving hospital work; and, though the proportion became far higher during the war, the requirement that everyone shall spend at least a year in such an appointment represents a major change in our educational system. It is brought within sight by the Bill to amend the Medical Acts which was introduced in the House of Lords last week. Under this Bill the student on qualification will be entitled only to provisional registration by the General Medical Council, which will demand evidence of twelve months' satisfactory resident (or virtually resident) work in an approved hospital or institution, including prescribed periods for medicine and for surgery, before full registration is granted. The hospital or institution is to be approved by one of the bodies empowered to grant a qualifying diploma or degree, and the Bill (unlike the Goodenough Committee) does not exclude recognition of a midwifery post for this purpose. A note by the Ministry of Health, which is responsible for the Bill, explains that much preliminary organisation will be needed before all this can be brought into effect. The Act will not operate until a day to be appointed by the Privy Council, and different days may be appointed for different parts of the British Isles. Under another clause of the Bill the General Medical Council will acquire for the first time the right to send visitors to report on the sufficiency of the courses of instruction given to medical students. At present its visitors do no more than inspect examinations.

So much for the educational aspects of the Bill. The remainder, which deals mainly with the constitution and disciplinary procedure of the council, has gained both positively and negatively by the modifications made in the four years since it was drafted for the consideration of the bodies chiefly concerned. It goes a very long way to satisfy the demands for reform which at one time became strong but have latterly faded through preoccupation with the National Health Service. While few have doubted that the council, with its 39 members, of whom 5 are appointed by the Crown, 27 by the universities and medical corporations, and only 7 are directly elected by the profession, is well fitted to perform its functions in respect of registrable qualifications and the issue of the *British Pharmacopœia*, it has been widely, and at times keenly, felt that such a body is not ideally constituted for judging errors of professional conduct. Under the Bill the members of the council are to be increased to 45, of whom 5 doctors and 3 laymen will be appointed by the Crown on the advice of the Privy Council. The number of members elected directly by the profession is increased only by 2—making 6 for England, 2 for Scotland, and 1 for Ireland—but at least 6 of them are to be members of the new Medical Disciplinary Committee on which the disciplinary functions of the council will now devolve. This committee, consisting of the president and 18 other members of the council (1 or more of whom must be non-medical) will work with a quorum of 9. Thus the elected members, who are generally in active practice, are formally granted a larger share in the judicial proceedings, and there will be less justification for the gibe that "even a medical practitioner is entitled to be tried by his peers, not by his professors."[1] We would respectfully ask the British Medical Association to consider whether, in these circumstances, it is desirable to continue the practice whereby the elected members of the General Medical Council are to all intents and purposes appointed by the council of the B.M.A. As things stand, an independent candidate would have to have quite exceptional claims before he could succeed against the B.M.A.'s official nominees, and we suggest that the elections would be given more reality and usefulness if the B.M.A., instead of asking voters to keep rigidly to an official list, were to present them with a choice of a dozen or more candidates all of whom would be acceptable to the association. If this incidentally improved the chances of an occasional outsider, so much the better both for the G.M.C. and the B.M.A.; for unreal elections are seldom quite healthy.

In the disciplinary procedure of the council—or rather of the Medical Disciplinary Committee—various important changes are made. Subject to the approval be better spent in planned debate. And if their results are as good as those of the microbiologists, they will be wise to publish them for the benefit of all.

Introduction to Clinical Perimetry (6th ed. London: Henry Kimpton. 1949. Pp. 332. 42*s.*).—The 6th edition of this work by Mr. H. M. Traquair, F.R.C.S.E., shows no major alterations, and indeed is so complete that none are possible. The visual pathways have been accurately traced from retina to occipital cortex; and, though the rare case may produce interesting findings, nothing can change the basic principles on which perimetry is founded, or alter the findings in a typical case. After some opening chapters on methods and apparatus, the author deals with the subject on an anatomical basis and gives examples of field defects due to disease or injury at all points of the visual nerve path. His book is accepted teaching in this and many other countries, and the standard is well maintained in the present edition.

Psychical Physics. *A Scientific Analysis of Dowsing, Radiesthesia and Kindred Divining Phenomena* (Amsterdam and London: Elsevir Publishing Co. 1949. Pp. 534. 60*s.*).—Prof. S. W. Tromp, the very industrious and candid author of this treatise, ranges far and wide in his search for evidence and explanation of water-divining. He gives his reasons for believing that there are created in and around living organisms and in the earth crust and the atmosphere electromagnetic fields, the interaction between which would account for the phenomenon of "divining." Some experiments of his own, conducted in laboratories in Holland, led him to conclude that a careful analysis of these and kindred happenings might prove to be of great value for medical research. Of this his book fails to persuade the medical reader, who—while cautiously mindful of Professor Rhine and extra-sensory perception—takes a less favourable view than Professor Tromp of certain reports—e.g., about Dr. Boyd's emanometer and Dr. Abrams's box. Such a reader doubts whether "radiesthesia" (divination by pendulums) can be of use in diagnosis and treatment, and is content to remain a sceptic so long as the data about divining and its necessary conditions and relevance to medicine are in the state which the reports here assembled disclose.

Physiology of the Uterus (2nd ed. London: Cassell. 1949. Pp. 611. 93*s.*).—In this work Mr. S. R. M. Reynolds, PH.D., a lecturer at Johns Hopkins University, supplies a connected account of what is known of the physiology of the uterine muscle. It is ten years since the appearance of the first edition, and in spite of the dislocation of research entailed by the war, much new material is available and needs assessing. There is no similar volume on this subject; it stands alone, and is wonderfully thorough. This edition is arranged differently from the first. The book is now divided into eight sections devoted to such subjects as uterine growth, functions and hormone control of the myometrium and uterine contractions, the circulation, metabolism and innervation of the uterus, and the onset of labour. In spite of the huge number of the original articles he has collected and consulted, Dr. Reynolds has produced a readable book of great interest to physiologists and to those who try to base their clinical work or clinical teaching on physiology. The whole is beautifully edited and presented, and contains some 70 illustrations. Dr. Reynolds has undertaken a task which will never be completed, and which will never allow him to rest. It was time someone accepted this heavy duty, for the gaps are perhaps larger in our knowledge of this branch of physiology than in any other. Doubtless this book has already stimulated much research.

his is the most that endocrine therapy can offer n dysmenorrhœa. At the meeting Mr. T. N. MacGregor claimed to have produced painless periods in 38 patients with spasmodic dysmenorrhœa by giving them œstrogen in the second half of the cycle. It is less easy to understand the underlying rationale of this method, especially as it is generally agreed that œstrogens given after the tenth day of the cycle have no demonstrable effect on the remaining events of the cycle and will not prevent menstruation from taking place at the expected time. It is probable that in the presence of progesterone exogenous œstrogens are in some way "inactivated," as they may be, and for the same reason, in pregnancy.

Prof. T. N. A. Jeffcoate made some sobering remarks on the use of œstrogens in pregnancy. He had reached the conclusion that they are fully effective only in preventing lactation and are less reliable in the suppression of established lactation. He doubted whether breast engorgement will respond to an occasional dose. If one was prepared to give them for up to seven days, he thought that œstrogens might assist in evacuating a missed abortion. He was convinced that œstrogen therapy has no part to play in the induction of labour; as much as 500 mg of œstradiol intravenously had been ineffective in a case of inertia. However, considerable interest has been taken in the work of the Smiths [4] on the œstrogen treatment of threatened and repeated abortions, toxæmia, and pre-eclampsia, and in Priscilla White's [5] report of a 90% fœtal survival-rate in 300 deliveries where the diabetic mothers had been treated with œstrogen during pregnancy. Olive Smith [6] claims success-rates of 72% in 219 cases of threatened abortion treated with œstrogen; 78% in 272 cases where the œstrogen was given prophylactically, on the basis of previous history, to prevent abortion: and 75% where it was given prophylactically again, on the previous history, to prevent complications of late pregnancy. For prophylaxis the Smiths insist on a rigid, gradually increasing, dosage schedule reaching 125 mg. of stilbœstrol daily by the 35th week. This is a very different schedule from that proposed by Christie Brown [7]—0·6 mg. of dienœstrol and 10 mg. of ethisterone daily up to the 18th week, after which the embryo should "plough its own furrow." Since 0·6 mg. of dienœstrol is equivalent to about 0·15 mg. of stilbœstrol the discrepancy is very wide. Christie Brown suggests that larger doses or a longer course of œstrogen may give rise to abnormality in the fœtus. He gives similar doses during the second half of the menstrual cycle in all cases of infertility showing no gross disease, to "secure firm implantation of the ovum," and 34% of 111 patients so treated became pregnant within six months. Here again is a method of treatment whose rationale is difficult to reconcile with the accepted physiology of the reproductive cycle, especially in relation to the behaviour of exogenous œstrogens and progestogens in the second half of the cycle. Yet it has yielded such surprisingly good results that one wishes the series had been statistically treated, for instance by giving alternate cases the active material and the placebo.

New Uses for Streptococcal Enzymes

The liquefying enzymes elaborated by some streptococci may well find increasingly wide applications in surgery and medicine, by aiding the removal of thick pus or other exudates from body cavities and surface wounds. Their uses have lately been reviewed by Tillett and his colleagues,[1] with striking colour photographs. Tillett and Garner[2] first described the fibrinolytic action of broth cultures of hæmolytic streptococci in 1933. Further studies of the liquefying process have shown [3] that the streptococcal fibrinolysin, which has been named streptokinase or SK, combines or reacts with a globulin factor present in serum or exudate, variously called plasminogen, serum protease, or activatable fibrin-lysing system, to form the active fibrin-lysing system or plasmin. Two years ago, Sherry, Tillett, and Christensen,[4] demonstrated that the physical characters of thick pus that make it difficult to aspirate are due not so much to fibrin as to desoxyribose nucleoprotein, which forms 30–70% of its total solids. They also showed [5] that the organisms producing streptokinase, such as the group A hæmolytic streptococci, can also produce desoxyribonuclease—now known as streptodornase or SD—which readily liquefies thick pus or viscous solutions of the nucleoprotein itself. Christensen [6] has since described an improved method for purifying these two enzymes: alcoholic precipitation is followed after solution by precipitation with protamine, and a further precipitation with 20% alcohol then brings down streptokinase and leaves desoxyribonuclease in solution. He also describes the somewhat formidable technique for estimating not only the two enzymes and plasminogen but also antistreptokinase, a normal constituent of blood-serum which inhibits streptokinase. The level of antistreptokinase in the blood is normally higher in adults than in infants, it is raised in rheumatic fever, and it reaches very high titres after the intrapleural injection of streptokinase.

Tillett and Sherry [3] have injected the purified enzymes into the pleural cavity in patients with different types of effusions, and the only toxic effects noted were some transient fever and malaise. In fibrinous pleurisy the aspirated fluid showed a fall in fibrinogen and a rise in non-protein nitrogen, sometimes accompanied by a leucocytic reaction. In most cases of empyema the enzymes rapidly reduced the amount of sediment in the pus and its viscosity, so that it could readily be aspirated; but in two cases the pus was sufficiently acid to inactivate the enzymes and no benefit was obtained. In postoperative hæmothorax the injection of streptokinase made it possible next day to aspirate much of the effusion as a thin brownish fluid. In the latest paper, Tillett et al.[1] mention two further cases of hæmothorax in which loculation or blood-clot hindered aspiration,

of the Privy Council. it is to make its own rules, deciding for example what rules of evidence should be observed. Unlike the present council, it may oblige witnesses to testify on oath, and command their presence by subpœna. It will, like the present council, be advised by a legal assessor, who will be a barrister, advocate, or solicitor of not less than ten years' standing, working under rules made by the Lord Chancellor. When the assessor advises the committee on any question of law he is to do so in the presence of all the parties to the proceedings (or their representatives); if the advice is given in camera, the parties shall be told what it was; and if the committee does not accept his advice the parties must again be informed. After so many years in which it has been advocated, a right of appeal from the council's decisions is at last granted; for within 28 days of hearing that his name is to be erased from the Register the practitioner may appeal to the Privy Council. These are large and welcome changes even if they do not at all points fulfil the suggestions put forward jointly by the defence societies.[2] Possibly the rules the committee will make will cover some of these—for example the need to ensure that (apart perhaps from the president) the members forming the tribunal shall not have previously considered the evidence as members of a penal-cases committee. The defence societies thought it advisable that in all cases the initial complaint should be supported by an affidavit or affidavits, and that "all evidence before the disciplinary tribunal be given orally on oath, save for good and sufficient reason, except evidence as to character which may be given in writing." More material was their recommendation that the tribunal should be able to administer other penalties short of erasure (namely, suspension for varying periods or censure of varying degrees); and we cannot help regretting that the Bill retains the phrase "infamous conduct in a professional respect" with its flavour of hanging, drawing, and quartering, instead of adopting the societies' term "professional misconduct." But with so much to approve there is no need to emphasise relatively minor points of disagreement.

Œstrogen Therapy in Menstrual and Pregnancy Disorders

THE limitations of œstrogen treatment in gynæcology and obstetrics are at last being more clearly defined. On the whole, the views expressed at the Royal Society of Medicine on March 17 were commendably cautious.

Dr. A. M. SUTHERLAND, discussing the 1000 cases of abnormal uterine bleeding in which he has examined the endometrium, emphasised the need for diagnostic curettage before endocrine therapy is decided on, for in 14% of the cases organic pathological lesions were found. On the other hand, of the remainder, nearly two-thirds showed no histological abnormality, and less than a third had any evidence of endometrial hyperplasia. These findings suggest that it is hardly justifiable to claim that some form of treatment has "cured" functional non-ovulatory uterine bleeding on the basis of normal endometrial or biphasic temperature pattern after treatment unless the non-ovulatory nature of the cycles was established before treatment. Where curettage reveals endometrial hyperplasia—the "metropathic" group—SWYER[1] has lately been advocating œstrogen therapy. The efficacy of high doses of œstrogen and progesterone in producing immediate hæmostasis during the bleeding phase—KARNAKY[2] originally advocated 10–25 mg. of stilbœstrol every 15 minutes until bleeding ceased within 4–6 hours—has been generally accepted. Such heroic dosage is seldom necessary, though it will often have to be a good deal higher than the 2–5 mg. daily recommended by SWYER to produce "obvious amelioration of the bleeding within 48 hours."

Most English gynæcologists would not expect more from endocrine therapy in menstrual disorders than the ability of œstrogen to check bleeding immediately, and the ability of progesterone, given in a non-bleeding phase and repeated at regular monthly intervals, to cause progesterone-withdrawal bleedings, thereby forestalling the onset of another metropathic bleeding phase. But SWYER has reintroduced the "Hamblen technique," consisting in œstrogen hæmostasis, "cycle development" by the production of œstrogen-withdrawal bleedings, and "pituitary regulation" with œstrogen followed by the combined administration of œstrogen and progesterone. HAMBLEN[3] claimed that this technique gives a 45% "salvage" rate in young women with functional uterine hæmorrhage, and that about half of those who do not react to the œstrogen-progesterone scheme will respond satisfactorily to his "one-two cyclic gonadotrophin therapy." SWYER has slightly modified HAMBLEN's technique, and he of course gives the œstrogens and progestogens by mouth, by which route they have for some time been proved effective in adequate doses. He has found secretory endometrium in all of his 8 cases in which initial biopsy showed a proliferative endometrium or cystic glandular hyperplasia. Unfortunately he does not tell us the interval between the two biopsies or the ages of the 8 patients. A claim of 100% success for any treatment is so impressive that it would have been interesting to know the details of each case. The basis of the cyclical progesterone-withdrawal treatment is the production of artificial "periods," as a substitute for irregular metropathic bleeding, until the metropathic condition undergoes spontaneous remission. Puberty bleeding is especially prone to such remissions; indeed, there are many cases in which only one prolonged and excessive bout of bleeding has ever occurred. Fortunately the metropathic type of maturity bleeding is also likely to undergo spontaneous remission. The possibility of these remissions must be borne in mind in evaluating the results of any form of treatment, and statistical analysis might sometimes be admissible.

Much has been written about the endocrine treatment of dysmenorrhœa. It seems clear that spasmodic dysmenorrhœa occurs only in ovulatory cycles, and that if ovulation is inhibited by giving œstrogen in the first half of the cycle the resulting withdrawal bleeding will be painless. (This simple fact has been amply proved by endometrial biopsy and by basal temperature records.) Many workers believe that

Whatever the explanation, it seems wise not to give pertussis vaccine if there is a past history of convulsions, if the child is suffering from or has recently had a respiratory or other infection, or he has lately been in contact with an infection to which he is susceptible.

DAY HOSPITALS

One out of every thirty-five people born in Great Britain (Dr. E. B. Strauss says[1]) is at some time or another a certified patient in a mental hospital. This is a dramatic way of putting the fact that the incidence of certifiable mental illness in the community is nearly 3%, and it certainly helps the imagination to grasp the problem in terms of people and families. Certified patients of course represent only a proportion of the mentally ill in the country: there are just as many people seeking voluntary treatment in our mental hospitals, and there are many more who do not need full hospital treatment but who badly need help of some kind. For some years now the mental service has been trying to find ways of helping these people. Outpatient clinics at mental and general hospitals do something, social clubs for discharged mental-hospital patients perhaps do more. Community care given by psychiatric social workers to patients in their own homes has already proved its worth[2]; and the day hospital started by the Institute of Social Psychiatry has benefited many who feel themselves to be in some sense outcasts from society—discharged patients, neurotics, psychopaths, and delinquents among them.

The institute opened its first social clubs for patients over ten years ago, and is now responsible for some 11 of them. The idea of a day hospital came to Dr. Joshua Bierer, the director of the institute, through his growing conviction that some of these patients needed more help than they gained from an hour or two a week, or even an hour or two a day, of social intercourse. The day hospital offers them fully occupied days: it provides group and individual treatment, occupational therapy throughout the day, art, music, and drama, and the opportunity to adapt themselves to a society which is, indeed, selected and experienced under safeguarded conditions, but which is nevertheless real—demanding appropriate behaviour and the acceptance of responsibility, and offering treatment at the level of actual personal experience. Every patient has his effect on the group: even withdrawal, as Dr. Strauss pointed out, has its effect, attracting some and repelling others. The day hospital thus differs from the mental hospital in providing an opportunity for emotional development. The inpatient can go his own way without affecting the group because he has no responsibility. The patient in a day hospital is one of a group in action: he gets the rewards or buffets which his own behaviour excites and he is directly affected by the behaviour of others.

It might be thought that society as a whole could provide him with this experience. It always had to do it in the past, and sometimes no doubt the results were good. The current unsociability of our race is responsible for a good deal of ostracism, and no doubt of expense. We have to make artificial opportunities for social intercourse for various groups of people—the aged, the residents of new housing estates, the mentally sick, the deaf, the blind, the troublesome, the lonely. In more genial days the general zest of society must have carried all these people along, and no-one seems to have been the worse. Now we withdraw our garments, and fear to be bored or distressed.

This has some bearing on the question raised by a probation officer at last week's conference: she asked whether there was no danger of "contamination": whether one neurotic would not confirm another in his symptoms—whether, in short, the day hospital was not brewing up an explosive mixture. Dr. Bierer was able to reply that they had not found it to be so, either in the clubs or the day hospital: but then they take their precautions, diluting the more explosive elements by getting their wives and families to join the clubs with them. In one experimental club where discharged criminals are members, psychiatric social worker students make the leaven. This particular club was actually started because discharged criminals can find no company but their own kind: nobody else will accept them, and this in itself predisposes them to offend again. The really antisocial person, Dr. Bierer said, cannot help fighting against society, because he feels like a cornered rat: "You will never remove his sense of being cornered by cornering him further." Our police, he reminded the meeting, carry no firearms: and fewer of them get killed than in any other country. Our criminals, he said, feel less cornered.

SOCIAL HISTORY OF THE WAR

Mr. Titmuss's *Problems of Social Policy*[1] is one of the United Kingdom Civil Series of the History of the Second World War. The basic data of his themes are simply stated:

> "One metric ton of high-explosive, dropped in night raids by piloted aircraft on large cities in Britain, killed about four to five people and injured between ten to fifteen. . . . When the raids came, the size and character of the problem of homelessness took the authorities by surprise. In general terms one ton of high-explosive delivered on the built-up area of London and other large cities destroyed or damaged beyond repair ten houses. Another twenty-five were rendered temporarily uninhabitable and eighty were slightly damaged. On the average, therefore, one ton affected 115 houses, made eighty people temporarily homeless and caused another thirty-five to lose their homes permanently. For every civilian killed, thirty-five were bombed out of their homes."

In sum, 60,000 civilians were killed, 86,000 were seriously and 149,000 slightly injured. 175,000 houses were destroyed, 201,000 were damaged and rendered uninhabitable for a period, and 3,034,000 had minor damage. Millions of citizens—expectant and nursing mothers and children—were evacuated from the danger areas under official schemes or privately. So strong was the pull of family life (and often so uncomfortable was the strain of living with strangers) that as the incidence of bombing dropped, so the evacuees tended to return, and as it waxed anew, so the evacuation process had to be repeated. But each time fewer went, and more effort was needed to persuade them to go.

So we have the three main themes of this book—the problems of evacuation, of the homeless, and of casualties—and in their unfolding Mr. Titmuss leads us both wide and deep. He divides his history into four parts: Expected War, The Invisible War, The Battles, and The Long Years. The pre-war plans, their shortcomings in face of the actual event, the effect on one another of evacuee and (often unwilling) host Treasury, parsimony, local-authority reluctance to incur expenditure, the poor-law traditions of "chargeability," the comparative blind spot on problems arising from housing damage, the transformation in outlook produced by the first week's blitz on London and the subsequent rapid development of post-raid services, the national nutrition policy, the excessive curtailment of some of and within 24 hours of the injection of streptokinase large volumes of blood were easily removed. In a patient with a postoperative effusion infected with *Ps. pyocyanea* more than a litre of bloodstained fluid was evacuated after the injection of streptokinase, but the remaining infection resisted all forms of treatment until streptodornase was injected on alternate days; after the third injection of this the pleura was sterile. It is thought that the removal of the exudate and debris allowed the natural antibacterial factors, cellular and humoral, to make better contact with the bacilli and to destroy them. Photomicrographs of pus from a maxillary sinus show how 20 minutes after the injection of streptodornase the whole background of debris in the film had disappeared, only living leucocytes being left. The enzymes were also useful in chronic osteomyelitis with sinus formation and spreading ulceration of the skin.

"Streptococcal enzymatic debridement," as TILLETT and his colleagues call their new technique for the removal of blood-clot and the cleansing of infected surfaces, is likely to be of great value as a supplement to antibiotic therapy in suitable cases, if only in shortening the patient's illness and lessening the formation of fibrous tissue. But it is clearly not a simple matter to arrange for the supply of the enzymes in adequate concentration, purity, and volume. This practical difficulty may be illustrated from the work of CATHIE [7] in this country. He has apparently had considerable success in the treatment of tuberculous meningitis by adding streptokinase to intrathecal injections of streptomycin. The enzyme was prepared by a modification of the method described by GARNER and TILLETT in 1934 [8]; the filtrate of the broth culture is adsorbed on to aluminium hydroxide and eluted with phosphate solution, and the product is standardised against clots formed in dilute plasma by the addition of thrombin. Even with this simpler method the routine supply of streptokinase is a considerable addition to the work of a hospital laboratory. Production by CHRISTENSEN's method of the presumably purer and more potent preparations, which are probably essential for the treatment of large pleural effusions, would be impracticable. The American workers say that much of their material was supplied by Messrs. Lederle and Co. and it is satisfactory to know that an active preparation of streptokinase can be obtained in England.*

Annotations

ENCEPHALOPATHY AND PERTUSSIS VACCINATION

CONVULSIONS are common in infants and young children, though they no longer appear among the major causes of child deaths. It has been estimated that 4–7% of apparently normal children have a convulsion before they are 5 years old. Most of these attacks are associated with pyrexial illnesses, particularly respiratory infections lasting only a day or two. Some 5–10% are followed by epilepsy in later life. Violent and focal convulsions often leave cerebral sequelæ, especially if they occur before the child is a year old, and Lennox,[1] who followed up 240 cases of febrile convulsions, found nervous instability of some kind in 10–15% of the children: she emphasised that fever with convulsions can produce brain damage detectable in an electro-encephalogram. A convulsion or coma is the most usual first symptom of the ill-defined group of cerebral disturbances called encephalopathies, and there seems to be no sharp dividing line between these and the postconvulsive state. In some of them there is a definite cause of cerebral irritation, such as lead-poisoning or uræmia, but in most cases the reason for the cerebral symptoms is obscure. Clinically it is difficult if not impossible to distinguish the encephalopathies associated with infections from postinfective encephalitis, and even the pathological differentiation is uncertain. Grouping these manifestations together it may be said that temporary, permanent, or even fatal cerebral disturbances occur in scarlet fever (Rolleston [2] collected records of 75 cases with hemiplegia), smallpox, measles, mumps, herpes zoster, typhoid fever, and pertussis. The cerebral symptoms usually appear with or after the rash, but Holliday [3] has lately published examples of "encephalitis" arising in the pre-eruptive stage of rubella, measles, and chickenpox, and this condition should be borne in mind whenever a child develops obscure neurological symptoms after being in contact with infection.

The most puzzling of the "encephalopathies" are those which follow prophylactic inoculations. Sometimes this is a chance association (there has been at least one instance of a child having a severe convulsion a quarter of an hour *before* a dose of vaccine), but smallpox vaccination and rabies or T.A.B. inoculations are undoubtedly, though very rarely, the cause of encephalitic symptoms. In the U.S.A. there have been reports of encephalopathy ascribed to pertussis vaccine, though again the incidence is very low in relation to the $2^1/_2$–3 million inoculations done every year. There have been no similar cases after diphtheria immunisation alone, which suggests that in the two recent cases in England following combined diphtheria-pertussis inoculation the pertussis vaccine was the cause. In both cases, oddly enough, the children had twin brothers who were immunised at the same time without ill effects. In both the injection was their first dose. The first case[4] was in a boy of 8 months who started a convulsion about eight hours after his injection and died in hospital seven or eight hours later. Autopsy showed only intense congestion and some œdema of the whole brain. In the case reported by Dr. Anderson and Dr. Morris last week (p. 537) the boy was older (2 years 7 months) and had had a convulsion with transient hemiplegia three months before, when other children in the house had mumps; his convulsions did not start until thirty-six hours after his immunisation. Fortunately this child recovered, though with a right hemiparesis; the encephalograms showed dilatation of the left lateral ventricle. The mechanism of these mishaps is unknown. *H. pertussis* does contain an endotoxin which, when injected into rabbits will cause death in convulsions: but this does not happen if the vaccine has been treated with heat or formalin, and presumably its action can be ruled out here. The possible explanations seem to be: "some sensitisation phenomenon"; a latent encephalopathic tendency, made manifest by the vaccine; a latent virus infection similarly activated; or a cerebral vascular accident, such as thrombosis of small cerebral vessels, which is supported by the rapidity of onset of the symptoms.

Reconstruction

WHAT MAKES A GOOD HOSPITAL?

(FROM A CORRESPONDENT)

WHAT makes a good hospital? It is strange to reflect that although we are now going forward with the creation of a national hospital service very few of those concerned with supervision of it could give a reasoned reply to the question. We are scarcely conscious of what we are trying to do when we speak of building up a good hospital service.

In common usage the word hospital signifies primarily the building. Many do not really get beyond this idea. A good hospital is, let us say, a clean bright modern building, typified for many by the much-publicised examples of new construction in Scandinavia, or the relatively few new modern units constructed in the '20s and '30s here in Great Britain. There is of course a measure of truth here: good work is hampered by obsolete premises suffering from the handicap of much improvisation. But it is only a short step from this to the idea that it is possible by voting a sufficient sum of money to plant a hospital here or there wherever the public need may require. This is, once stated, plainly a fallacy. It leads straight to an emphasis on construction, regardless of the need first to ensure that men and women are going to be available to staff the hospital. A better appreciation of the things that go to make a good hospital may save much heart-burning later.

FIVE ELEMENTS

It is probably fair to say that, apart altogether from physical premises, there are five main elements on which the merit of a hospital depends. Three of them have been recognised as essential to the conception of a hospital in this country ever since the refoundation of the Royal hospitals in the 16th century—namely:

(1) A medical staff.
(2) A nursing staff, together with the necessary complement of cooks, domestic workers, and so forth.
(3) An administrative authority.

To these there have been added since the latter years of the 19th century two still only half-understood essentials:

(4) Diagnostic facilities, and the staff to operate them.
(5) A social welfare service.

No-one is properly qualified to take a share in the supervision of hospital services who has not at least some understanding of what constitutes excellence in each of these five respects. And how many of those recently appointed to act on regional boards and hospital management committees have more than a dim idea of what is needed? To be able to detect an occasional human failing here and there in an existing organisation is not enough; the old half-conscious methods of the past will surely fail in this new era unless we have a clear concept of what is needed.

What then constitutes excellence in these five directions? It is impossible without writing a book to do more than offer a few observations under each heading and to hope that they may prove suggestive.

THE FIRST THREE

Excellence in the Medical Staff

The medical staff must comprise the best men available and they must work happily as a team. As to the ways of ensuring this, the tradition of our best hospitals has been clear and forthright now for many generations. The staff have been elected by their colleagues, acting together as the medical committee of the hospital, and there should be the least possible interference with this procedure. The method admittedly carries with it the danger of inbreeding—and the arrangements now devised to enable the regional boards to have control of the medical appointments may be a necessary safeguard; but if they destroy the sense of comradeship among the medical staff the gain will have been dearly bought, and the arrangements must be revised before it is too late. (This, in all its ramifications, is a large and difficult subject; one wonders whether the experimental character of the new arrangements has been explained to the members of the regional boards who have been invited to operate it.)

With the highest standards of professional skill must go one other thing of the utmost importance to a hospital—an absolute integrity towards every patient. We like to think that the tradition enshrined in the charge to the physicians at St. Bartholomew's—enjoining them to set aside "all favoure, affection, gayne or lucre"—needs no repetition today. Is the record spotless? The excellence of a hospital depends in no small measure on a refusal to allow this great British tradition to be compromised by the arrival within the walls of the hospital of the pay-bed patient. Publicity is here perhaps the best safeguard. Let *all* paying patients' fees (to the medical staff as well as to the hospital) be collected through the hospital office, and let a statement of all payments made be laid regularly before the board of governors or a small subcommittee chosen for the purpose.

Excellence in the Nursing Staff

Here there is to hand a simple test. With certain exceptions it is true to say that a good hospital is one that is not short of nurses—that is to say, one to which women of the right kind are attracted in sufficient numbers. Nurses come and go, and they know their hospitals with an intimacy impossible to the outsider. If the nursing staff is up to complement, then the nursing in that hospital is pretty sure to conform to our British standards of excellence. The converse is not equally true, for there are exceptions—and the hospitals for tuberculosis are a case in point—where it would be wrong to judge the quality of the nursing by this test. Generally speaking, a hospital which is periodically short of nurses—and more especially if other hospitals of apparently similar character are not equally short—should leave no stone unturned to discover why, even if inquiry leads to difficult and awkward conclusions.

In no department is the hospital more dependent on the human factor than in its matron and her nurses. A good nursing staff is one that is happy: and there is no doubt whatever that women differ immensely in their capacity as matrons (and as ward sisters) to achieve this sense of harmony. Not every appointment is a success. It is a weakness in our system that it is not always easy financially for a matron or a ward sister to retire upon pension, and something can often be done to make this a little easier.

I must not here embark on a discussion of the wider nursing questions—whether the centralised examination system and other trends of the times obscure the essence of hospital nursing as the relief of distress and the comforting of the patient, or write on the danger of *diverting* the emphasis to ward routines and semimedical technicalities. But it may be permissible to observe that one short cut now increasingly adopted—the employment of young girls to look after the aged and chronic sick—is certainly no sign of excellence in a hospital. Of all our present practices, this employment of child labour is surely the most certain to be condemned by the opinion of the future.

Excellence in Administration

He who would understand what constitutes good hospital administration *must* know something of the change which has come over the scene within the last thirty or the social services in the danger areas and their inadequate and tardy development in the reception areas —these are a few of the topics which Mr. Titmuss, as social historian, illuminates as he pursues his main themes.

The story of the Emergency Medical Service and the Casualty Service naturally occupies a significant though not a preponderating part of the book. The natural anxiety to be ready at all times to deal with war casualties, whether Service or civilian, led to severe curtailment of resources available to the sick civilian. This shortage was encouraged by the financial arrangements inevitably made by the Ministry of Health to reserve beds for war victims. The strain fell particularly heavily on sick children, on the old, on the mentally sick, and on a large proportion of the tuberculous, who were discharged home to help create a reserve of beds. In due time these emergency arrangements had to be modified, but the main burden of caring for the civilian sick was borne by the then "municipal" hospitals. This is well shown by the figures Mr. Titmuss gives of vacant to occupied beds in February, 1941, which was 1 : 0 9 in the voluntary hospitals as against 1 : 8·0 in the municipal. But the experience gained led as early as 1942 to a Government promise of a post-war national hospital service, and the now historic hospital surveys were begun. And so with other social services. Designed in a hurry to meet the emergencies of war, they have now passed into the fabric of the national life.

Mr. Titmuss gives some interesting illustrations of the indirect price of war in terms of human life. Deaths of babies in 1940–41 showed an excess of 6500 over those of 1938–39; 130 children, indulging their natural play instincts, were accidentally drowned in emergency water tanks in 1940–43; in elderly people between 1940 and 1943 there was an excess mortality of 2300 from "falling downstairs, out of bed, elsewhere in the home, out of doors, or from unknown circumstances." But out of suffering came wisdom. Perhaps the most striking proof of that in the field of social policy was the arrest of the downward trend in vital statistics which marked 1940 and 1941, and the subsequent achievement, while the war was still in progress, of records which would have appeared impossible in 1938. The author quotes René Sand: "We can buy human life. Every country within certain limits decides its own death rate."

Mr. Titmuss has already put social medicine in his debt by his statistical analyses of infant mortality and by his social studies, with Prof. Fred Grundy, of Luton. His present lucid and well-written book is a really important work of social history. As such, it adds incidentally but profoundly to the raw material of social medicine and substantially increases our indebtedness.

ADOLF MEYER

THE development of psychiatry in the United States and Canada, and in this country, during the present century probably owes more to Adolf Meyer than to any other single man. Many forces, historical and contemporary, unifying and disruptive, have given it the diverse shapes it wears today, but none has exerted the steady formative central pressure upon its theory and practice which Adolf Meyer's teaching in the Henry Phipps Clinic afforded the generations of men and women who in their turn passed on to their students the broad conceptions and detailed practice which they had learnt from Meyer at Johns Hopkins. Among them were most of the abler psychiatrists of America, and many from Great Britain and the Commonwealth who hold prominent teaching positions. Adolf Meyer's death on March 16, therefore, has historical as well as personal significance. Psycho-analysis now plays a larger part in psychiatric training and theory than he conceded it, and the short-cut physical methods of treatment are often at odds with his insistence on paying full attention in therapy to the whole man and all the circumstances that could have caused or could maintain a mental illness. But the main stream still runs in the channel he cut. Our rapidly growing knowledge of cerebral physiology and its bearing on mental disease moreover is in no sense alien to his way of regarding the relationship of bodily to mental happenings.

Strangers often found it hard to understand why Adolf Meyer was the undisputed leader of American psychiatry for decades. He wrote little himself and never produced a comprehensive textbook or statement of his teaching; his exact researches were chiefly concerned with cerebral anatomy and pathology; his pupils published comparatively little from his wards and laboratories; he was difficult to follow because of his ungrateful and laboured style; and no outstanding advance in nosology, therapy, or psychopathology was linked with his name. Yet the paradox was immediately explained when one came under his personal influence. He was a psychiatrist who might well have been taken as the ideal type of what such a specialist should be—humane, alert, warm-hearted, shrewd and sensible, medically and scientifically in the great tradition; a teacher at once exacting and stimulating; a man with a social conscience and a wise humility. To causes such as the furtherance of mental hygiene he gave farsighted support, while remaining critical of unbalanced enthusiasms. In so far as psychiatry in the English-speaking countries is now a respected and indispensable part of medical training and practice, it is the work in considerable measure of Adolf Meyer, through his teaching and example.

IODINE IN SALT

DOMESTIC salt is in future to contain iodide. This news, reported in our parliamentary column, was given on March 22 by Mr. Maurice Webb, the Minister of Food, who intimated that he would follow the recommendations of the Food Standards Committee of the Ministry of Food. This committee has proposed that all prepacked salt should contain potassium or sodium iodide in amounts equivalent to not less than 15 and not more than 30 parts of iodine per million parts of salt. To minimise loss of iodine, iodised salt should be packed in containers resistant to the effects of humidity changes, and packages should be date-st [illegible] the manufacturer. It has proved [illegible] to iodise block salt.

The promised action springs from the findings of the Medical Research Council. The goitre subcommittee[1] urged in 1944 that salt should be iodised; and the need was further underlined in 1948.[2] It was not possible to act at once on these reports; and as an interim step iodine was added to vitamin preparations issued to expectant mothers from welfare centres. At present only about 1·6% of prepacked salt is iodised, and it will probably be rather more than two years before all is treated in this way; but it is good news that such a simple safeguard is at last to be extended to all.

THE INDEX and title-page to *Vol. II, 1949*, which was completed with THE LANCET of Dec. 31, is published with our present issue. A copy will be sent *gratis* to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam Street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive indexes regularly as published should do so now.

Reconstruction

WHAT MAKES A GOOD HOSPITAL?

(FROM A CORRESPONDENT)

WHAT makes a good hospital? It is strange to reflect that although we are now going forward with the creation of a national hospital service very few of those concerned with supervision of it could give a reasoned reply to the question. We are scarcely conscious of what we are trying to do when we speak of building up a good hospital service.

In common usage the word hospital signifies primarily the building. Many do not really get beyond this idea. A good hospital is, let us say, a clean bright modern building, typified for many by the much-publicised examples of new construction in Scandinavia, or the relatively few new modern units constructed in the '20s and '30s here in Great Britain. There is of course a measure of truth here: good work is hampered by obsolete premises suffering from the handicap of much improvisation. But it is only a short step from this to the idea that it is possible by voting a sufficient sum of money to plant a hospital here or there wherever the public need may require. This is, once stated, plainly a fallacy. It leads straight to an emphasis on construction, regardless of the need first to ensure that men and women are going to be available to staff the hospital. A better appreciation of the things that go to make a good hospital may save much heart-burning later.

FIVE ELEMENTS

It is probably fair to say that, apart altogether from physical premises, there are five main elements on which the merit of a hospital depends. Three of them have been recognised as essential to the conception of a hospital in this country ever since the refoundation of the Royal hospitals in the 16th century—namely:

(1) A medical staff.
(2) A nursing staff, together with the necessary complement of cooks, domestic workers, and so forth.
(3) An administrative authority.

To these there have been added since the latter years of the 19th century two still only half-understood essentials:

(4) Diagnostic facilities, and the staff to operate them.
(5) A social welfare service.

No-one is properly qualified to take a share in the supervision of hospital services who has not at least some understanding of what constitutes excellence in each of these five respects. And how many of those recently appointed to act on regional boards and hospital management committees have more than a dim idea of what is needed? To be able to detect an occasional human failing here and there in an existing organisation is not enough; the old half-conscious methods of the past will surely fail in this new era unless we have a clear concept of what is needed.

What then constitutes excellence in these five directions? It is impossible without writing a book to do more than offer a few observations under each heading and to hope that they may prove suggestive.

THE FIRST THREE

Excellence in the Medical Staff

The medical staff must comprise the best men available and they must work happily as a team. As to the ways of ensuring this, the tradition of our best hospitals has been clear and forthright now for many generations. The staff have been elected by their colleagues, acting together as the medical committee of the hospital, and there should be the least possible interference with this procedure. The method admittedly carries with it the danger of inbreeding—and the arrangements now devised to enable the regional boards to have control of the medical appointments may be a necessary safeguard; but if they destroy the sense of comradeship among the medical staff the gain will have been dearly bought, and the arrangements must be revised before it is too late. (This, in all its ramifications, is a large and difficult subject: one wonders whether the experimental character of the new arrangements has been explained to the members of the regional boards who have been invited to operate it.)

With the highest standards of professional skill must go one other thing of the utmost importance to a hospital —an absolute integrity towards every patient. We like to think that the tradition enshrined in the charge to the physicians at St. Bartholomew's—enjoining them to set aside "all favoure, affection, gayne or lucre"—needs no repetition today. Is the record spotless? The excellence of a hospital depends in no small measure on a refusal to allow this great British tradition to be compromised by the arrival within the walls of the hospital of the pay-bed patient. Publicity is here perhaps the best safeguard. Let *all* paying patients' fees (to the medical staff as well as to the hospital) be collected through the hospital office, and let a statement of all payments made be laid regularly before the board of governors or a small subcommittee chosen for the purpose.

Excellence in the Nursing Staff

Here there is to hand a simple test. With certain exceptions it is true to say that a good hospital is one that is not short of nurses—that is to say, one to which women of the right kind are attracted in sufficient numbers. Nurses come and go, and they know their hospitals with an intimacy impossible to the outsider. If the nursing staff is up to complement, then the nursing in that hospital is pretty sure to conform to our British standards of excellence. The converse is not equally true, for there are exceptions—and the hospitals for tuberculosis are a case in point—where it would be wrong to judge the quality of the nursing by this test. Generally speaking, a hospital which is periodically short of nurses—and more especially if other hospitals of apparently similar character are not equally short—should leave no stone unturned to discover why, even if inquiry leads to difficult and awkward conclusions.

In no department is the hospital more dependent on the human factor than in its matron and her nurses. A good nursing staff is one that is happy: and there is no doubt whatever that women differ immensely in their capacity as matrons (and as ward sisters) to achieve this sense of harmony. Not every appointment is a success. It is a weakness in our system that it is not always easy financially for a matron or a ward sister to retire upon pension, and something can often be done to make this a little easier.

I must not here embark on a discussion of the wider nursing questions—whether the centralised examination system and other trends of the times obscure the essence of hospital nursing as the relief of distress and the comforting of the patient, or write on the danger of diverting the emphasis to ward routines and semimedical technicalities. But it may be permissible to observe that one short cut now increasingly adopted—the employment of young girls to look after the aged and chronic sick—is certainly no sign of excellence in a hospital. Of all our present practices, this employment of child labour is surely the most certain to be condemned by the opinion of the future.

Excellence in Administration

He who would understand what constitutes good hospital administration *must* know something of the change which has come over the scene within the last thirty or the social services in the danger areas and their inadequate and tardy development in the reception areas —these are a few of the topics which Mr. Titmuss, as social historian, illuminates as he pursues his main themes.

The story of the Emergency Medical Service and the Casualty Service naturally occupies a significant though not a preponderating part of the book. The natural anxiety to be ready at all times to deal with war casualties, whether Service or civilian, led to severe curtailment of resources available to the sick civilian. This shortage was encouraged by the financial arrangements inevitably made by the Ministry of Health to reserve beds for war victims. The strain fell particularly heavily on sick children, on the old, on the mentally sick, and on a large proportion of the tuberculous, who were discharged home to help create a reserve of beds. In due time these emergency arrangements had to be modified, but the main burden of caring for the civilian sick was borne by the then "municipal" hospitals. This is well shown by the figures Mr. Titmuss gives of vacant to occupied beds in February, 1941, which was 1 : 0·9 in the voluntary hospitals as against 1 : 8·0 in the municipal. But the experience gained led as early as 1942 to a Government promise of a post-war national hospital service, and the now historic hospital surveys were begun. And so with other social services. Designed in a hurry to meet the emergencies of war, they have now passed into the fabric of the national life.

Mr. Titmuss gives some interesting illustrations of the indirect price of war in terms of human life. Deaths of babies in 1940–41 showed an excess of 6500 over those of 1938–39; 130 children, indulging their natural play instincts, were accidentally drowned in emergency water tanks in 1940–43; in elderly people between 1940 and 1943 there was an excess mortality of 2300 from "falling downstairs, out of bed, elsewhere in the home, out of doors, or from unknown circumstances." But out of suffering came wisdom. Perhaps the most striking proof of that in the field of social policy was the arrest of the downward trend in vital statistics which marked 1940 and 1941, and the subsequent achievement, while the war was still in progress, of records which would have appeared impossible in 1938. The author quotes René Sand: "We can buy human life. Every country within certain limits decides its own death rate."

Mr. Titmuss has already put social medicine in his debt by his statistical analyses of infant mortality and by his social studies, with Prof. Fred Grundy, of Luton. His present lucid and well-written book is a really important work of social history. As such, it adds incidentally but profoundly to the raw material of social medicine and substantially increases our indebtedness.

ADOLF MEYER

THE development of psychiatry in the United States and Canada, and in this country, during the present century probably owes more to Adolf Meyer than to any other single man. Many forces, historical and contemporary, unifying and disruptive, have given it the diverse shapes it wears today, but none has exerted the steady formative central pressure upon its theory and practice which Adolf Meyer's teaching in the Henry Phipps Clinic afforded the generations of men and women who in their turn passed on to their students the broad conceptions and detailed practice which they had learnt from Meyer at Johns Hopkins. Among them were most of the abler psychiatrists of America, and many from Great Britain and the Commonwealth who hold prominent teaching positions. Adolf Meyer's death on March 16, therefore, has historical as well as personal significance. Psycho-analysis now plays a larger part in psychiatric training and theory than he conceded it, and the short-cut physical methods of treatment are often at odds with his insistence on paying full attention in therapy to the whole man and all the circumstances that could have caused or could maintain a mental illness. But the main stream still runs in the channel he cut. Our rapidly growing knowledge of cerebral physiology and its bearing on mental disease moreover is in no sense alien to his way of regarding the relationship of bodily to mental happenings.

Strangers often found it hard to understand why Adolf Meyer was the undisputed leader of American psychiatry for decades. He wrote little himself and never produced a comprehensive textbook or statement of his teaching; his exact researches were chiefly concerned with cerebral anatomy and pathology; his pupils published comparatively little from his wards and laboratories; he was difficult to follow because of his ungrateful and laboured style; and no outstanding advance in nosology, therapy, or psychopathology was linked with his name. Yet the paradox was immediately explained when one came under his personal influence. He was a psychiatrist who might well have been taken as the ideal type of what such a specialist should be—humane, alert, warm-hearted, shrewd and sensible, medically and scientifically in the great tradition; a teacher at once exacting and stimulating; a man with a social conscience and a wise humility. To causes such as the furtherance of mental hygiene he gave farsighted support, while remaining critical of unbalanced enthusiasms. In so far as psychiatry in the English-speaking countries is now a respected and indispensable part of medical training and practice, it is the work in considerable measure of Adolf Meyer, through his teaching and example.

IODINE IN SALT

DOMESTIC salt is in future to contain iodide. This news, reported in our parliamentary column, was given on March 22 by Mr. Maurice Webb, the Minister of Food, who intimated that he would follow the recommendations of the Food Standards Committee of the Ministry of Food. This committee has proposed that all prepacked salt should contain potassium or sodium iodide in amounts equivalent to not less than 15 and not more than 30 parts of iodine per million parts of salt. To minimise loss of iodine, iodised salt should be packed in containers resistant to the effects of humidity changes, and packages should be date-stamped before leaving the manufacturer. It has proved technically impracticable to iodise block salt.

The promised action springs from the findings of the Medical Research Council. The goitre subcommittee[1] urged in 1944 that salt should be iodised; and the need was further underlined in 1948.[2] It was not possible to act at once on these reports; and as an interim step iodine was added to vitamin preparations issued to expectant mothers from welfare centres. At present only about 1·6% of prepacked salt is iodised, and it will probably be rather more than two years before all is treated in this way; but it is good news that such a simple safeguard is at last to be extended to all.

Disabilities

48. THE MENTALLY HANDICAPPED CHILD

THE knowledge that one's child is not developing normally usually comes very slowly, beginning with a nagging fear and growing like a dark cloud as the months go by. Because of this the natural tendency is to break away from the menace and refuse to face the situation. In these days the child-welfare clinics are a great help to the young mother: but there are many who avoid the clinic, as well as friends, from the time when they first realise that their baby is not doing the things that a normal child does at his age. This is a great pity because every moment is valuable and if the situation is there to be faced, and the task to be done, the sooner one begins on it the better.

When my baby was a year old she had cut no teeth and made no attempt to sit up: she just lay and smiled placidly, and sucked all her food. She had had a very prolonged birth, and although I did not realise it at the time, had had pressure on the brain which would partially disable her for the rest of her life.

By the time she was two we had found a doctor who put us in touch with expert advice and we learned that we were faced with an uphill task, but one that we were assured had promise of achievement. Those were the darkest days of all because they were so full of uncertainty. It was difficult to believe in a promise that the child would eventually walk and talk. She was two-and-a-half before she walked at all, and then awkwardly and with a dragging movement. By the time she was four, when my next baby was born, I was still—in spite of persistent attempts at training—washing nappies, and coping with dirty beds. She had teeth now, but no desire to use them for purposes of mastication. I am afraid I laughed somewhat bitterly when the specialist said that she would one day be a 75% good citizen: but his words encouraged me, and I kept on with that queer doggedness that is nature's gift to mothers.

We tackled the problem of clean habits by a vigilance that must have irritated the child as much as it did us, for at last the miracle happened. At night we tried every method that anyone suggested and at last found our own particular answer to the trouble. For a period we lifted her every 2 hours, then every 3, working on to 4, and so on, until finally she went from 10 P.M. until 6 A.M., and the battle was as good as won. We found in this, as in other things, that rhythm and routine are the only substitutes for an active brain.

Feeding was a difficulty that was to concern us for many years. First of all because we had to teach the child to chew by means of games, constant facial contortions, and exaggerated movement of our jaws. Even after the first essential was grasped, this was a thing we had to watch for years. Then she had to be taught to feed herself. Her hands were spastic, and she found it difficult to hold a spoon—impossible to find her mouth. Our method here was to play with a spoon at times other than meal times—to have a bowl of lentils or peas, and try to ladle them from one dish to another. Then, when the art of holding the spoon was achieved, the next move was to put honey on the spoon, and guide it to her mouth. After we had tried a few goes at this, she made a rough (very rough) attempt at finding her mouth for herself: and the washing of face, head, and garments that this entailed was well worth while. By the age of seven an onlooker at a party had no idea that there was anything wrong. A party with cream cakes and jelly is a pretty good test!

The first walking was, as I have said, very awkward. Here I owe a big debt to a series of dancing teachers who have given exercises and remedial drill which have done wonders. These exercises have not been merely for feet and legs, but for hands and arms, and general harmony of movement. I believe that the coordination of bodily movement has done much to help her with speech. The use of the hands is very important too. We did not start with a pencil, but with a long paintbrush which was easy to hold, and required the movement of the whole arm. From this we went on to coloured pencils, and when the child was able to hold a pencil properly we went on to form. My method may seem strange but it worked. We put two dots on a piece of paper, and, imitating train-noises, we travelled from one to the other. Sometimes the line made some extraordinary journeys in between, but eventually we travelled the shortest distance. Then we used four dots and at last we got the shape of a primitive house. The curl of smoke that we added to the chimney was Mother's exclamation mark of triumph! We have now travelled through many stages—through crude woolwork, raffia-work, felt-work—up to the ultimate triumph of making Mother a frock at the local L.C.C. dressmaking class: and it is wearable! More than that: this year another miracle happened when a kind friend taught the art of toy-making, and by the sale of soft-toys actual money has been earned towards the summer holidays. This was something I had never contemplated. What if it *has* taken twenty-one years?

Speech meant a long journey, too. Here again I owe much to a speech specialist who helped not only my child but me as well to tackle this big problem. My advice to parents of children with retarded speech is talk to your child: talk, and keep on talking. Point out things, even if he doesn't seem to respond. Talk clearly and in simple words. At one time I was afraid people would think I was a foreigner—because I mouthed my words and I spoke so deliberately and distinctly. Lip-control is usually poor with retarded children, and there are many useful exercises for this which can be turned into games: blowing a ping-pong ball across a polished table is one, and another is to make a miniature clothes-line and pin paper clothes on it which must be blown dry by a strong wind. At 4½ my child could only say "Daddy." At her twenty-first birthday party she replied (in a memorised speech, it is true) to her toast. Speech may never become perfect, but so long as it frees the child to express himself it is worth waiting for.

One essential is to let the child lead as normal a life as possible. Perhaps there is a tendency to keep him in the background and confine him to the home. One has to fight one's pride and make a bid for normal contacts; and I have always found other children kind—anyhow up to the age of adolescence, when they become too much occupied with their own affairs. Then one has to depend on the friendship of older people. If it is possible for the child to have at least some corporate lessons in whatever kind of school is possible, that is a good thing; but I found that the actual teaching must be done individually. We had a teacher for some years whose methods were worth noting. For example, she told the story of Dick Whittington, then my little girl read the story in a very simplified form. Next, since we are fortunate enough to live in London, they went up to see the Mansion House and the Royal Exchange. After that they went down to the river and watched a ship unload its cargo. The story had become visual and alive. The next day they talked about it, trying to remember what they had seen. Then they read the story again, and the words in the book were shapes of something real, and therefore remembered.

The development of independence is a subject in itself. The beginning is difficult because the backward child lacks initiative, and has to be persuaded, cajoled, and led. It would be so much easier to do up his shoes, wash his hands, and comb his hair one's self; and it is forty years. Until the end of the 19th century, administration of a hospital was relatively simple: it was quite possible for a more or less uninstructed committee of lay folk to raise funds for a hospital, meet and appoint and dismiss the subordinate staff, and make sure that the cost of provisions was not excessive. The guardians managed the poor-law hospitals on similar but more economical lines, though they usually leaned more heavily upon the medical superintendent and sometimes took too much for granted. But with the increase in the complications of hospital management, it has become no more possible for a committee to administer a hospital successfully without a knowledgeable administrator than it is possible for such a body to manage an ordinary money-making business employing an equivalent number of staff. The committee must choose an executive officer and give him their confidence. It is his business to advise them on the whole economy of the hospital understood in its widest sense. The experience of the best hospitals in Great Britain and America over the last generation is decisive in this matter: but we have still many hospitals where the older tradition prevails and the executive officer is regarded as a mere clerk, whose duty is believed to be to place every matter that calls for a decision before the management committee.

A good administration implies that the just degree of delegation to the executive officer and his staff is established and maintained. It must vary according to circumstances, and the human factor cannot be left out of account. If the executive officer does not "carry the guns" needed for the task, it may be necessary for the chairman and other members of the committee to come to the rescue and help him out. If his personality is too marked, it may be necessary to exert some restraint and see that he does not unduly dominate the matron and other officers of the hospital. But the management of the hospital must not be taken out of his hands, for no hospital can be well administered if the committee continually overrules the policies of its executive officer.

Medical staff, nursing staff, and administrative officers—these three constitute the nucleus of any hospital. They must work happily together as a team, and to enable them to do so within the limits prescribed by the budget is the primary function of the committee. The three elements do not automatically achieve this sense of unity; for each—if it is alive and active as it should be—must be regarded as a potential source of pressure on the organisation as a whole. In periods when medicine is changing as it is changing today, the medical staff are constantly making fresh demands upon the nursing staff, and on the administration. The shifting stresses and strains must be accepted and welcomed as signs of life, and not regarded as something to be resisted or resented.

TWO OTHERS

There remain however, as noted above, at least two other components which cannot in these days be left out of account in assessing the quality of a hospital—its diagnostic facilities and its social-welfare services. Neither are entirely new developments, for both came into being during the latter years of the 19th century: but neither are so well established as essential parts of a hospital worthy of the name that their quality—or even their existence—can be taken for granted.

Excellence of Diagnostic Facilities

"Do not show me your wards and your kitchens: show me your laboratories!" said Sir William Osler to a hospital conference of 1910. It is a fair guess that if he were with us today he would still find much to criticise. The development of diagnostic facilities (by which I mean the X-ray departments and the various pathological and other laboratories) has been rapid but spasmodic, and the quality of the services provided by different hospitals is hard to assess. Experts in these fields tend to get on with their own job in their own hospital and do not make a habit of going round inspecting the deficiencies in other hospitals. And yet the efficiency of its diagnostic facilities and the professional quality of the personnel in charge of them is a sure guide to the capacity of a hospital to keep in step with progress. In no other field would the disparities between the different hospitals, if they were faithfully tabulated, prove so staggering.

Probably one of the most useful things that any regional board could do would be to arrange for a periodical inspection of the diagnostic facilities provided by the hospitals within its province. In this field there is no known means of ensuring that the personnel of any particular hospital can determine for themselves whether or not they are abreast of progress or stagnating in a backwater.

Excellence of Social-welfare Services

The choice of a social-welfare service as a sine qua non of a good hospital may seem a little strange when so much else of importance is omitted. What of the physiotherapy and other therapeutic services? What of the standard of catering, and so on? But the choice is deliberate. There is nowadays no reasonable room for doubt but that a hospital which takes patients and sends them out again without almoners to see that the patient is, as far as may be, free from worry while in hospital and helped along on the right road after departure, is just not doing its job. Nor is there any reasonable doubt but that this work amounts to a major department of the hospital, guided by its own criteria, requiring its own specialised staff, and—although not everyone would agree with this—properly responsible through the administrative officer to the governing body of the hospital. (Others would say that the department is a mere appanage of the medical staff, to whom it owes its allegiance; but the weakness of this approach is surely that it would limit the work of the almoner to the case referred by the doctor, whereby much that is important would inevitably be missed.)

What is at stake is not merely the existence of an almoner's department; it is a conception of the function of the hospital. For too long the hospital has been regarded as little more than the workshop of the surgeon and the physician, and the nurse has had to circumscribe her station to keep in line: the appearance on the scene of the almoner reintroduces an element of solicitude for the hospital's guests without which the modern hospital cannot discharge its duty to the community.

"... A doctor is, by definition, a man who doesn't have time. One of the things the average doctor doesn't have time to do is catch up with the things he didn't learn in school, and one of the things he didn't learn in school is the nature of human society, its purpose, its history, and its needs.... If medicine is necessarily a mystery to the average layman, nearly everything else is necessarily a mystery to the average doctor. Medical education is uniquely narrow, intense, and protracted. The doctor is the specialist *par excellence.* And his specialization doesn't end with his entrance into practice. The developments in medicine come so fast that the conscientious practitioner has no time to interest himself in the common concerns of citizens.... The doctor—the average doctor—is a nice fellow to have around the house or the hospital. His self-sacrifice for his patients is proverbial and proverbially true. But he sometimes breaks down in the larger areas of social intercourse because his training and his calling break down there. And the medical calling, like others that deal with bodies *qua* bodies, has a peculiar attraction to the socially circumscribed personality."
—MILTON MAYER, *Harper's Magazine*, December, 1949.

With the object of drawing attention to the desirability of securing national and international agreement on the colouring and marking of cylinders and the use of non-interchangeable regulating valves, the Association of Anæsthetists convened a meeting at the Royal College of Surgeons on Jan. 25, which was attended by representatives of the Ministry of Health, the Royal College of Surgeons, the Royal College of Obstetricians and Gynæcologists, the Association of Anæsthetists, the British Standards Institution, the Faculty of Anæsthetists, the British Medical Association, the British Dental Association, the Medical Defence Union, and the World Medical Association. Dr. John Gillies was in the chair. The following resolutions were passed unanimously:

1. That this meeting, in view of the number of deaths resulting from incorrect coupling of medical gas cylinders, strongly recommends that non-interchangeable couplings for medical gas cylinders as described in the draft code of practice agreed by the technical committee (CHE/20) of the British Standards Institution, be introduced at the earliest possible moment.
2. That representations be made to the Ministry of Health and that a copy of the decision of this meeting with regard to the adoption of the non-interchangeable coupling be sent to the Ministry for information and action.
3. That this meeting endorses the British Standards Institution's request that the Ministry of Health should approach the American Bureau of Standards.
4. That those present at this meeting should approach their opposite numbers in the United States of America.
5. That those present should meet again in four months time to receive reports on the progress of the steps taken.
6. That the above resolutions should be published in the medical and dental press and communicated to the medical departments of the Services, who should be asked to approach their opposite numbers in the United States and the Dominions.

Parliament

Midwives (Amendment) Bill

In the House of Lords on March 21 Lord SHEPHERD moved the second reading of this Bill. Only a small proportion of the 63 recommendations of the Working Party on Midwives[1] necessitated new legislation, and by far the greater number were being put into effect administratively. At present there were 70,000 midwives in England and Wales on the roll, but under 18,000 were practising. Of these, 5800 were employed by hospital authorities and 8200 by local authorities.

Turning to the Bill itself Lord Shepherd said that the first two clauses dealt mainly with the reconstruction of the Central Midwives Boards for England and Scotland. Hitherto they had been appointed by Order in Council but the Government had now decided to ask Parliament to allow changes in the boards to be made by statutory instrument. Any changes which might be made in the constitution of the boards would not imply a reflection on their efficiency, but would be designed to strengthen them, possibly by the inclusion of a higher percentage of qualified midwives, who were now limited to 5 out of a membership of 14 in England and Wales. Clauses 3 and 4 concerned the reciprocal recognition between the English and Scottish boards, clause 5 the recognition of women trained outside the United Kingdom. Where their training was not regarded as sufficient the Central Midwives Board would be able to authorise further training to justify the issue of a British certificate. Clause 6 dealt with the provision of an official uniform which would not, however, be compulsory. But the penalty for wearing a uniform without authority would be severe. Clause 7 dealt with the roll of midwives. Since so few of the women inscribed were actually in practice it was considered a waste of money to continue to publish it every five years. But the roll would be kept at C.M.B. headquarters, and local authorities would supply the central boards with the names of practising midwives and it would be their duty to publish these lists every year—17,000 names instead of 70,000. Clause 8 enabled the local supervising bodies to provide residential accommodation for pupil midwives.

Appointments to Hospital Management Committees

In the House of Commons on March 21 Mr. J. A. BOYD-CARPENTER raised on the adjournment what he described as "certain rather odd happenings in the South West Metropolitan Regional Hospital Board," which gave rise to interesting reflections on what was happening generally on the hospital side of the National Health Service. He thought that the general policy of the Ministry of Health not to intervene in the actions of the regional boards was right, but in the case he was about to describe non-intervention by the Minister would amount to connivance of a grave abuse in the regional hospital board's powers. The dispute had arisen in connection with the appointments to the Kingston group management committee: and in the background there was another dispute between the group management committee and the regional board on whether the Kingston Victoria Hospital should continue as a small hospital where general practitioners might treat their patients or whether it should be turned into a maternity unit attached to a larger hospital.

The question had now arisen of the renewal of appointments to the management committee; the chairman and three of the members had not been reappointed. They were all people who had strongly supported the views of their own management committee against the views of the regional board. Mr. Boyd-Carpenter suggested that the board had used their powers of appointment to force their views upon the management committee. It was laid down by the National Health Service Act that before filling vacancies the board should consult the committee. He understood that consultation had not taken place.

At the same time, he continued, the local advisory committee had been asked for recommendations for appointments to the group committee. They nominated four medical men in order of preference. The regional board appointed the last two and it was perhaps significant that the doctor whose name appeared first shared the views of the group management committee on the future of the Victoria Hospital. It was equally interesting to note that there remained on the group management committee a doctor who was not only a member of the regional board but also an employee of the group management committee.

Mr. FRED MESSER hoped, that the Minister would not give in to this appeal. The boards could not possibly do their job if they always had to be looking behind their shoulders to see whether what they were doing met with the Minister's approval. If the Minister permitted an inquiry into this case every regional board would be faced with this prospect when it declined to renew an appointment.

Mr. BLENKINSOP, parliamentary secretary to the Ministry of Health, was sorry that Mr. Boyd-Carpenter had indulged in what he could only describe as special pleading. The Minister had no power to deal with the appointment of hospital management committees; that was the statutory job of the regional hospital boards. The Ministry were satisfied that the regional hospital board here had carried out its duties to the letter and there was no basis at all for the Minister to intervene in any way. They wanted to encourage the regional boards to bring new personnel into the management committees.

Medical Bill

On March 22 Lord Shepherd introduced a Bill to amend the Medical Acts, and for purposes connected therewith. The Bill was read a first time.

QUESTION TIME

Iodised Salt

Mr. SOMERVILLE HASTINGS asked the Minister of Food whether the Food Standards Committee had yet completed their inquiry into the measures necessary to give effect to the Medical Research Council's recommendation that all domestic salt supplies in Great Britain should be iodised as a measure of protection against goitre.—Mr. MAURICE WEBB so very difficult to refrain from doing it again when it has been clumsily and badly done.

---

[1] See *Lancet*, 1949, i, 190.

The most difficult stage in the struggle to give him independence is when the child has to be trained to do things outside the home by himself. The first day (and for many days afterwards) that a small figure walked to school alone, I walked, heavily disguised, on the other side of the road. There are certain risks you must take if your child is going to have a life worth living.

Later on, when my little girl was trained in road sense, she learned to shop—at first with someone, and later alone. This is a great joy to her. If the name of anything is difficult we write it down, and since she is not too clever about money she always has more than enough in her purse, and in coins of large denomination.

Lethargy is an enemy that has to be watched, especially during the years when the accomplishments are few. We have always tried to keep her active and interested without unduly tiring her; and as the things that she could do mounted up this vigilance became less necessary.

During the difficult years the child may feel frustrated. I found that attempts to counteract this by praising her for accomplishment had to be very judicious. It is, however, important to let the child feel that, at least in the home, she is a person of significance. There are many simple jobs and responsibilities that will give this sense of mattering which every human being needs. Never mind if the cups get broken or the milk spilt. The aim is not to achieve perfection, but to give the child a chance of growing up into a person able to do some service, not only for himself, but for the community.

Special Articles

HEALTH SERVICE ESTIMATES

The gross cost of the National Health Service in Great Britain during 1950–51 is estimated at £464,514,400. This figure is given in the Civil Estimates[1] published last week.

For England and Wales the gross cost is estimated at £413,260,400 (compared with £400,183,432 in 1949–50); and the net cost, allowing for appropriations-in-aid at £351,541,000 (compared with £317,873,250 in 1949–50). For Scotland the figures are: gross cost £51,254,000 (compared with £49,988,300 in 1949–50); and net cost £41,394,000 (compared with £40,636,300 in 1949–50). Thus the net increase is £33,667,750 for England and Wales; and £757,700 for Scotland.

For England and Wales the following estimates of gross cost are given:

	1950–51 £	*1949–50* £	*Increase* £	*Decrease* £
Central Council, &c.—	5000	2500	2500	—
Hospital, specialist, and ancillary services—	237,980,100	221,994,600	15,985,500	—
Services provided by local health authorities—	17,180,000	14,320,000	2,860,000	—
General medical and dental services, pharmaceutical services, and supplementary ophthalmic services—	140,394,000	141,487,400	—	1,093,400
Training services, &c.—	63,600	56,250	7350	—
Other services—	*17,637,700*	*22,322,682*	—	*4,684,982*
Total ..	413,260,400	400,183,432	18,855,350	5,778,382

The allotment to the hospital, specialist, and ancillary services in England and Wales is distributed as follows:

	1950–51 £	*1949–50* £	*Increase* £
Advances to regional hospital boards—	193,415,000	184,375,000	9,040,000
Advances to boards of governors of teaching hospitals—	34,470,000	31,565,000	2,905,000
Capital expenditure by the Minister in the acquisition of land, hospitals, and equipment—	3,300,100	2,016,200	1,283,900
Payments to the Minister of Pensions—	4,020,000	2,222,000	1,798,000
Payments to the Minister of Works—	1,594,000	*993,000*	*601,000*
Expenses of the Minister in connection with research—	31,000	30,800	200
Bacteriological service, &c.	1,150,000	792,600	357,400
Total	237,980,100	221,994,600	15,985,500

Under the heading of general medical and dental services, pharmaceutical services, and supplementary ophthalmic services, the distribution in England and Wales is as follows:

	1950–51 £	*1949–50* £	*Increase* £	*Decrease* £
Administration—	1,929,500	1,858,000	71,500	—
General medical services—	42,734,000	41,745,000	989,000	—
Pharmaceutical services—	28,003,000	31,700,000	—	3,697,000
General dental services—	41,565,000	43,048,000	—	1,483,000
Supplementary ophthalmic services—	*25,665,000*	*22,725,000*	*2,940,000*	—
Medical Practices Committee—	9000	8000	1000	—
Dental Estimates Board—	487,000	402,000	*85,000*	—
Tribunal under section 42 of the 1946 Act—	*1500*	*300*	1200	—
Transferred liabilities—	—	1100	—	1100
Total ..	140,394,000	141,487,400	4,087,700	5,181,100

Among other services in England and Wales, the cost of compensation for loss of the right to sell medical practices is estimated at £5,315,000, compared with £7,165,000 in 1949–50.

MEDICAL GAS CYLINDERS

The Association of Anæsthetists of Great Britain and Ireland and the Medical Defence Union have interested themselves for some time in safety measures to eliminate, as far as possible, avoidable anæsthetic deaths. With this object in view, these two bodies have collaborated with the British Standards Institution in preparing a code of practice for anæsthetists, and in addition have approved certain recommendations concerning the colouring and marking of cylinders containing gaseous anæsthetics. Most of the changes suggested are immediately practicable, and together they form a short-term policy.

As a long-term policy, there have been prepared, with the assistance of the manufacturers of anæsthetic gases and apparatus, specifications for standardised non-interchangeable couplings and coloured leads; and it is hoped that when these come into general use, wrong connections between gas cylinders and anæsthetic or inhalational apparatus will be virtually impossible and deaths from such accidents avoided.

It is eminently desirable, however, that these couplings should be adopted by international agreement which has not yet been obtained. There is also disagreement internationally as to the colouring and marking of cylinders. This is a matter of great significance in wartime: lack of inter-Allied uniformity led to many unfortunate occurrences during the late war.

---

[1] Civil Estimates for the Year ending March 31, 1951. *Class V*: Health, Housing, Town Planning, Labour, National Insurance, and Contributions to Local Revenues. H.M. Stationery Office. Pp. 154. 3s. 6*d*.

With the object of drawing attention to the desirability of securing national and international agreement on the colouring and marking of cylinders and the use of non-interchangeable regulating valves, the Association of Anæsthetists convened a meeting at the Royal College of Surgeons on Jan. 25, which was attended by representatives of the Ministry of Health, the Royal College of Surgeons, the Royal College of Obstetricians and Gynæcologists, the Association of Anæsthetists, the British Standards Institution, the Faculty of Anæsthetists, the British Medical Association, the British Dental Association, the Medical Defence Union, and the World Medical Association. Dr. John Gillies was in the chair. The following resolutions were passed unanimously:

1. That this meeting, in view of the number of deaths resulting from incorrect coupling of medical gas cylinders, strongly recommends that non-interchangeable couplings for medical gas cylinders as described in the draft code of practice agreed by the technical committee (CHE/20) of the British Standards Institution, be introduced at the earliest possible moment.
2. That representations be made to the Ministry of Health and that a copy of the decision of this meeting with regard to the adoption of the non-interchangeable coupling be sent to the Ministry for information and action.
3. That this meeting endorses the British Standards Institution's request that the Ministry of Health should approach the American Bureau of Standards.
4. That those present at this meeting should approach their opposite numbers in the United States of America.
5. That those present should meet again in four months time to receive reports on the progress of the steps taken.
6. That the above resolutions should be published in the medical and dental press and communicated to the medical departments of the Services, who should be asked to approach their opposite numbers in the United States and the Dominions.

Parliament

Midwives (Amendment) Bill

IN the House of Lords on March 21 Lord SHEPHERD moved the second reading of this Bill. Only a small proportion of the 63 recommendations of the Working Party on Midwives[1] necessitated new legislation, and by far the greater number were being put into effect administratively. At present there were 70,000 midwives in England and Wales on the roll, but under 18,000 were practising. Of these, 5800 were employed by hospital authorities and 8200 by local authorities.

Turning to the Bill itself Lord Shepherd said that the first two clauses dealt mainly with the reconstruction of the Central Midwives Boards for England and Scotland. Hitherto they had been appointed by Order in Council but the Government had now decided to ask Parliament to allow changes in the boards to be made by statutory instrument. Any changes which might be made in the constitution of the boards would not imply a reflection on their efficiency, but would be designed to strengthen them, possibly by the inclusion of a higher percentage of qualified midwives, who were now limited to 5 out of a membership of 14 in England and Wales. Clauses 3 and 4 concerned the reciprocal recognition between the English and Scottish boards, clause 5 the recognition of women trained outside the United Kingdom. Where their training was not regarded as sufficient the Central Midwives Board would be able to authorise further training to justify the issue of a British certificate. Clause 6 dealt with the provision of an official uniform which would not, however, be compulsory. But the penalty for wearing a uniform without authority would be severe. Clause 7 dealt with the roll of midwives. Since so few of the women inscribed were actually in practice it was considered a waste of money to continue to publish it every five years. But the roll would be kept at C.M.B. headquarters, and local authorities would supply the central boards with the names of practising midwives and it would be their duty to publish these lists every year—17,000 names instead of 70,000. Clause 8 enabled the local supervising bodies to provide residential accommodation for pupil midwives.

Appointments to Hospital Management Committees

In the House of Commons on March 21 Mr. J. A. BOYD-CARPENTER raised on the adjournment what he described as "certain rather odd happenings in the South West Metropolitan Regional Hospital Board," which gave rise to interesting reflections on what was happening generally on the hospital side of the National Health Service. He thought that the general policy of the Ministry of Health not to intervene in the actions of the regional boards was right, but in the case he was about to describe non-intervention by the Minister would amount to connivance of a grave abuse in the regional hospital board's powers. The dispute had arisen in connection with the appointments to the Kingston group management committee: and in the background there was another dispute between the group management committee and the regional board on whether the Kingston Victoria Hospital should continue as a small hospital where general practitioners might treat their patients or whether it should be turned into a maternity unit attached to a larger hospital.

The question had now arisen of the renewal of appointments to the management committee; the chairman and three of the members had not been reappointed. They were all people who had strongly supported the views of their own management committee against the views of the regional board. Mr. Boyd-Carpenter suggested that the board had used their powers of appointment to force their views upon the management committee. It was laid down by the National Health Service Act that before filling vacancies the board should consult the committee. He understood that consultation had not taken place.

At the same time, he continued, the local advisory committee had been asked for recommendations for appointments to the group committee. They nominated four medical men in order of preference. The regional board appointed the last two and it was perhaps significant that the doctor whose name appeared first shared the views of the group management committee on the future of the Victoria Hospital. It was equally interesting to note that there remained on the group management committee a doctor who was not only a member of the regional board but also an employee of the group management committee.

Mr. FRED MESSER hoped that the Minister would not give in to this appeal. The boards could not possibly do their job if they always had to be looking behind their shoulders to see whether what they were doing met with the Minister's approval. If the Minister permitted an inquiry into this case every regional board would be faced with this prospect when it declined to renew an appointment.

Mr. BLENKINSOP, parliamentary secretary to the Ministry of Health, was sorry that Mr. Boyd-Carpenter had indulged in what he could only describe as special pleading. The Minister had no power to deal with the appointment of hospital management committees; that was the statutory job of the regional hospital boards. The Ministry were satisfied that the regional hospital board here had carried out its duties to the letter and there was no basis at all for the Minister to intervene in any way. They wanted to encourage the regional boards to bring new personnel into the management committees.

Medical Bill

On March 22 Lord Shepherd introduced a Bill to amend the Medical Acts, and for purposes connected therewith. The Bill was read a first time.

QUESTION TIME

Iodised Salt

Mr. SOMERVILLE HASTINGS asked the Minister of Food whether the Food Standards Committee had yet completed their inquiry into the measures necessary to give effect to the Medical Research Council's recommendation that all domestic salt supplies in Great Britain should be iodised as a measure of protection against goitre.—Mr. MAURICE WEBB replied: The Medical Research Council after extensive examination have recommended that all table and cooking salt should be iodised for the prevention of goitre and thyroid enlargement. This recommendation has been endorsed by the Ministry of Health Standing Committee on Medical and Nutritional Problems, and it has the full approval of the Secretary of State for Scotland and the Minister of Health.

---

[1] See *Lancet*, 1949, i, 190.

The Food Standards Committee were asked to advise on what measures would be necessary to give effect to the medical recommendation. They have recently completed their inquiries and have recommended a standard of composition for iodised salt which can be enforced by chemical analysis. The committee received evidence from representatives of the salt industry, who have concurred in the recommendation as a permanent measure, and from other expert witnesses, and have advised that within one year from the date of an order all pre-packed free-running salt should be treated with small traces of iodide and that within two years all other pre-packed salt should be similarly treated. I understand that this would mean that the production of cut-lump salt would have to be discontinued. I am advised that if salt production as between pre-packed free-running salt and other salt used in the home remains substantially in the same proportion as in 1948 slightly more than half the population of Great Britain would benefit within the first year from the Medical Research Council's recommendation and that the entire population would benefit by the end of two years. Steps will not be taken to give effect to the Committee's recommendations until all concerned (the trade and technical interests, the medical profession and, indeed, the public) have had full opportunity to make any representations they wish. The Food Standards Committee will be open to receive representations until June 30, 1950.

Hospital Management Committees

Mr. DONALD KABERRY asked the Minister of Health whether, in view of the experience now gained as to the working of the hospital management committees and the filling of casual vacancies, he was prepared to review the rules governing the constitution of these committees, with a view to securing more adequate public representation.—Mr. ANEURIN BEVAN replied: The appointments are a matter for the regional hospital boards, who are required by statute to ensure that each committee includes members appointed after consultation with certain specified local public bodies. They are not, however, required by statute to undertake such consultations on the occurrence of every casual vacancy.

Motor-cars for Disabled Miners

Mr. EMRYS HUGHES asked the Minister what steps he was taking to provide motor-cars to disabled miners similar to those provided for disabled soldiers.—Mr. ARTHUR BLENKINSOP replied: Motor propelled tricycles are provided for severely disabled civilians under the National Health Service, but I cannot undertake to provide motor-cars.

Foods for Diabetics

Wing-Commander E. E. BULLUS asked the Minister if he would arrange that special foods prepared for diabetic people should be supplied as medical necessities under the National Health Scheme.—Mr. BEVAN replied: I am afraid this is not possible. The Act of 1946 authorises the provision of all proper or sufficient drugs and medicines but does not cover the provision of foods.

Health Centres

Mr. SOMERVILLE HASTINGS asked the Minister of Health what arrangements he had made for practitioners who are willing to undertake full-time service in health centres in any part of the country to secure an opportunity to practise their profession in this way, and what steps he took to ensure agreement by suitable practitioners of a district to undertake service in a health centre before he sanctioned the provision of such a centre by new construction or adaptation.—Mr. ANEURIN BEVAN replied: Before approving a health centre I obtain an assurance from the executive council, after consulting the local medical committee, either that enough local doctors want to practise there or that the need for more doctors in the area would justify advertising vacancies. Mr. HASTINGS: Does not the Minister think that if he agreed to the arrangement suggested in the first question, it would greatly improve the distribution of doctors, which is most unequal at present?—Mr. BEVAN: A special committee of the Central Health Services Council is exploring the whole question of the lines on which health centres should be developed.

In answer to a further question, Mr. BEVAN stated that one new building for a health centre was under construction, one other new building and one adaptation had been approved, and other schemes were under consideration. He had no information as to the numbers of doctors willing to transfer their practices to health centres. The present building situation would in any case make it impossible to provide health centres for all doctors who would like it.

Number of Nurses

Replying to a question, Mr. BEVAN said that the total nursing and midwifery staff employed whole-time or part-time in the National Health Service in England and Wales on Dec. 31, 1949, was 174,000. This was 12,000 more than on Dec. 31, 1948.

Hospital Boards and Committees

Mr. BOYD-CARPENTER asked the Minister whether it was with his approval that paid servants of regional hospital boards or group hospital management committees are appointed members of the particular boards or committees by whom they are employed.—Mr. BEVAN *replied*: As a general principle, I am not in favour of these officers serving as members of the bodies with which they are immediately connected. The requirements of the Acts make it inevitable, however, that a limited number of the senior medical and dental staffs should be so appointed, and I recognise that there may be other exceptional cases where it is desirable so to appoint officers.

Unemployed Doctors

Replying to a question, Mr. GEORGE ISAACS stated that there were at present 74 unemployed medical practitioners on the Appointments Register. This number included 36 foreign doctors, most of whom are Polish.

Poliomyelitis and Inoculation

Mr. S. P. VIANT asked the Minister of Health whether in view of the admitted risk of postvaccinal encephalitis he would consider making an investigation with the object of ascertaining if the numerous inoculation operations now being performed are playing any part in causing poliomyelitis.—Mr. BEVAN replied: I will consider the suggestion.

Fat Content of Ice-cream

Mr. SOMERVILLE HASTINGS asked the Minister of Food whether he would make regulations designating two or more qualities of ice-cream according to fat content, so that the public might have knowledge of the food value of the article purchased.—Mr. MAURICE WEBB replied: I am afraid that shortage of ingredients still make it impossible to introduce a satisfactory single standard for ice-cream without seriously reducing supplies to the public. The Food Standards Committee has considered fixing two standards; but after consulting the trade and the local-authority associations they felt that the lower standard, to which most of the manufacturers would have had to conform, would not have a good enough food value. In the circumstances, the committee recommended that the introduction of standards should be deferred until an improvement in the supply of rationed ingredients made it possible to prescribe a satisfactory minimum standard.

Public Health

Smallpox

A NURSE in a Glasgow hospital sickened on March 23, developed a rash on March 25, and has now been diagnosed as having semiconfluent smallpox. By last Monday the diagnosis of smallpox had been confirmed in two other cases, both modified by previous vaccination. In addition. two adults and a baby were under observation.

The source is probably a Goanese seaman who landed from R.M.S. *Chitral* at Tilbury on March 5 and travelled to Glasgow. He felt unwell on March 7 and developed a rash soon after admission to hospital on March 10. Chickenpox was diagnosed by competent physicians. This man was probably infected on the *Chitral* and there may be another missed case or cases amongst the passengers and crew who disembarked in London on March 5.

Smallpox should be suspected in any passengers or contacts who report fever or rashes to their doctors.

In England Now

A Running Commentary by Peripatetic Correspondents

THIS tension in the air about the atom bomb and worse takes us in different ways. Many avoid mentioning it at all; most rational people say soberly what they think, but do not dwell on it. Some optimists maintain that the danger is greatly exaggerated. The reaction which surprised me most came from a retired senior civil servant. He and my husband were at Oxford together and are renewing their old friendship. In the course of a long, scholarly, and intimate talk together the international situation naturally came up. Like many others the learned man evidently thought (erroneously) that the husband of a doctor knows more about drugs than other men do. "Do you know of a strong narcotic poison?" he asked, for he thought such a thing might be useful. My husband, having resigned to me the hyoscine preparation with which he flew back from America, said truthfully that he did not. "I believe one can be prepared from the roots of runner beans," said his friend wistfully. True, the ancients disliked beans and thought them unlucky, but Yeats spoke for us moderns in prizing his nine rows. Yet now the world has grown so sinister that a sane and quiet householder can turn his thoughts from scarlet and white flowers with bees murmuring among them, and from succulent green slices accompanying roast meat and gravy, to the poison underground which may deliver him from unknown horrors.

* * *

A character in *South Wind* remarks: "Mothers at present can bring children into the world, but this performance is apt to mark the end of their capacities . . . It is quite surprising how many survive in spite of their mothers. Ask any doctor." Norman Douglas might have known our hamlet. Regardless of the fact that I am not a G.P., they come blithely along hoping I will provide treatment and reassurance and so save them a visit to the village or town, for their own doctors will not come out without good cause. There were three of these mothers in one week not long ago.

The first came one morning to say that Barbara was being very sick and could I suggest anything? I gave her an alkali for an immediate stomach washout, and, as soon as I had arranged that the lunch would go on cooking in my absence (for it was a day when I had no help), I walked round. Barbara might have eaten something outré, for she is a schoolfellow of that would-be Sophie Tuckshop of ITMA who has figured before in these pages, or she might have some more serious ailment which would mean sending for their own doctor. The little girl was in the living-room wrapped in her mother's fur coat—a curious covering for a vomiting child, I thought. She was very limp, but her eyes were bright and her tongue clean; she complained of pain "here," comprehensively over the epigastrium, and there was no tenderness or rigidity; then she obligingly vomited into the kitchen sink, so I could see there was only clear fluid and a grape or two, duly skinned and stoned. She denied having eaten anything unusual. Then the mother volunteered that Barbara had felt sick after school treacle pudding the day before, and she had therefore given her two aspirins at bedtime and another that morning at breakfast. So the unfortunate child of 9 had had gr. 15 in about twelve hours and it seemed her tummy had revolted. I was discoursing on the use and abuse of aspirin when the father came in from outside and heard me. "Aspirin?" he said. "It always makes me sick, and I daren't touch it now." This seemed to clinch the diagnosis, especially since I had myself seen and spoken to the little girl the previous evening, not long before bedtime and the administration of the gr. 10 of aspirin; she had then been cavorting about the road on a borrowed bicycle outside my garden and seemed to be in perfect health. I thought to myself that a woman who has been married for eleven years should know something by now of the idiosyncrasies of both husband and child, and that aspirin is not a panacea.

A few days later a baby of fifteen months arrived in the arms of anxious parents. Toddling about the sitting-room, the floor strewn with toys, her three elder sisters, and the feet of three adults, she had sat down suddenly and let out a yell. She was wearing neither knickers nor napkin, and something sharp had made a gash of about half an inch on one labium. She was picked up bleeding and brought by car the hundred yards to my house, such was the agitation of the parents. It was not a deep cut and nothing was necessary but bathing and something to keep the labia from sticking, and I applied penicillin ointment. We never found out what she had sat on; opinions differed between the sharp corner of the fender and the tag of a shoe lace. The place healed rapidly and the mother, a doctor's daughter, promised meekly not to let baby run about in future naked from the waist down. It seems to me to be a very bad habit among what one may call the less fastidious mothers to dispense with protection for a child's nether regions as soon as sphincter control is gained. No doubt it saves washing knickers, but it is not hygienic, it may lead to infection, and the tender skins and genitals of toddlers are easily hurt when they sit down Bump, as they are apt to do.

The third little girl, aged three, came weeping in her mother's arms and accompanied by the grandmother. She wanted to pass water and couldn't, as they said in their soft country burr—and as she called out piteously in baby language. There was nothing to see, they were sure, but when I pulled down her knickers and looked, she was red and sore. She had these attacks after eating apples and tomatoes, they said, and she had been eating apples. "Well, why let her eat them?" I asked. Their broad, kind, subthyroid faces looked at me perplexed. For the same reason, I knew but again did not say, that a certain mother of a diabetic boy in pre-insulin days gave him chocolates; the child wanted them.

The question for all these and many other mothers is "Why?" But there will be no reply.

* * *

The other day I ran across this advertisement in a back number of one of the American journals:

> "SCRUB NURSE desires position with surgeon. Boston or vicinity. Postgraduate course and scrubbing experience in neuro-, thoracic and general surgery."

My little dictionary defines "scrub" (verb) as "to rub hard with something coarse or bristly"; and "scrub" (noun) as "brushwood, stunted trees, insignificant person, stunted animal or plant." One would scarcely expect that a nurse would advertise that she was an insignificant person, or that she could tell the forest from the trees because the latter were stunted. Nor would she be useful in surgery because she could rub hard with something coarse, unless a hog was to be operated on; her talents would scarcely be employed on exposed nerves or cerebrum. Actually a "scrub nurse" is an operating-theatre sister privately employed by a surgeon to assist him in institutions where the services of regularly employed sisters cannot be furnished, or in instances where the surgeon prefers to have his own "scrub nurse."

* * *

The doctor's telephone seems to have been forgotten when the National Health Service Act was being put together. It lays down (I suppose) that the doctor shall see his N.H.S. patients at the surgery at stated hours and visit them when they are too unwell to get to the surgery; but it says nothing about answering their futile questions on the phone. Many ci-devant private patients still ring me up at all hours just to chat about my latest prescription or ask me to get them some of the new drug they have read about in the *Daily Whatnot*. When my brain was picked in this way before the Act I could, if sufficiently irritated, add a bit to the bill: now I can only say: "I'll be in my surgery at such and such a time" and hang up. Of course, these patients don't like that. I suppose they are the same thoughtless types who buttonhole doctors at cocktail parties and tell them about their illnesses in the Far East or Mother's Terrible Operation. Can't we have another Amending Act to deal with them?

Letters to the Editor

GENERAL PRACTICE TODAY

AN APPRECIATION

SIR,—It is a good military principle that after a reconnaisance has been made but before action is taken an appreciation shall be made of the situation. So although it is true that Dr. Collings, in concluding his illuminating report, does summarise his findings and gives his own individual recommendations for action, he will doubtless not begrudge one of that group whom he calls "the people most concerned—namely 'ordinary' general practitioners" the right to make an independent appreciation of his report and to suggest the action it might or should provoke.

My own first impression, which I find is shared by others, was that Dr. Collings's method of sampling must have thrown up a greater proportion of the bad than of the good in general practice in England, so that the picture it gave him was distorted. Then I realised that this was really unimportant. What mattered was that Dr. Collings had found practices existing in England of the bad types he describes; and had been able to observe the bad effect that working under such conditions had had on men who had come from their hospitals well trained, well qualified, and with good clinical disciplines. "The conditions and conduct of general practice in industrial areas make a mockery of our modern medical education and the disciplines and practices taught in our great hospitals." It is true that these practices Dr. Collings condemns existed before the coming of the National Health Service; it is equally true that the service has done nothing to abolish them and much to perpetuate and even to multiply their incidence.

If I read Dr. Collings aright, he believes that the industrial practitioner today is carrying too great a load, and often attempting to do this in insufficient premises, with poor equipment and inadequate ancillary help. He rarely has easy access to hospital diagnostic departments and even less often to hospital beds. In such circumstances, no matter how sincere his first intentions, it is fatally easy for him and his patients to come after a few years to accept a standard of hasty interview, spot diagnosis, and the transference of all cases of real responsibility to the care of the specialist services at the hospital as the best that general practice can offer.

At present it seems to be nobody's business to help him to do better work. The executive council attends only to the day-to-day administration of the service. It initiates nothing. It acts in no way as the protector of the general practitioner—neither by encouraging the local health authority towards health-centre provision, nor by discouraging the hospital management committees from abrogating the help their hospitals have so long had from the practitioner. As for the regional hospital boards "their attitude to the problems presented by industrial practice was one of resignation to the inevitability of that sort of thing, of hopelessness of doing anything about it at its source, and of consequent acceptance of the need to compensate for it through the agency of hospital and specialist services."

The bright thing about the Collings report is that Dr. Collings refuses to accept "the inevitability of that sort of thing" and believes that if the general-practitioner service is seen whole, and planned properly, there is scope for a much better service, and hope for the future, provided that "instead of continuing a policy of compensating for its deficiencies, we should admit them honestly and try to correct them at their source."

Chief among the deficiencies revealed as needing correction are ill-planned and ill-equipped practice premises; the heavy load of patients and lack of ancillaries which together rob the practitioner of time and opportunity to use his special skills; and the lack of opportunity for coöperation with colleagues in general or specialist practice. It is salutary to realise how many of these major deficiencies might have been alleviated if only we had been able to develop the health centre. Dr. Collings is well aware of this, and there is little doubt he is right in suggesting that the organisation of basic group practice units should be encouraged even in advance of any health-centre building programme. If such units could be helped to employ proper ancillary staff, and to coöperate better with hospital and local-authority services, the worst factors now depressing general practice might well be alleviated And as money, materials, and labour do become available for building we should plan some inexpensive buildings in which these group-practice units could work, and so correct the present tendency to plan on the one hand elaborate expensive unattainable all-purpose health centres, or on the other, traditional buildings intended only for health-authority clinics.

Dr. Collings does not lay much stress upon the effects of our methods of payment of the doctors. He does not find any reason to believe that payment by capitation fee materially changes the doctor-patient relationship. Nevertheless, it must be recognised that payment made solely on a quantitative basis encourages the building of large practices and commensurately diminishes the time available for the investigation and treatment of each patient. Almost certainly we will have to find a way of reducing the handicap and hardship now borne by the man with the small list. Had the extra millions claimed by the General Medical Services Committee been available, their proposed distribution as an increased capitation fee on the first thousand patients on a principal's list might have done much to make practice with smaller lists economically possible, and also to create more places for principals in practice. Even now a reconsideration of the distribution of the practitioners' fund is called for. It is, for instance, possible that by making the fixed annual payment (at its present or at an enhanced rate) a central and not a local charge something could still be done and done at once to help to introduce new doctors to areas most needing them, and to alleviate the problems of the areas where lists are never likely to grow large.

To all this must be added a closer association for the general practitioner with his local hospital, with ease of access to diagnostic departments, and greater opportunity to follow, discuss, and understand the investigation and treatment of his patient in hospital ward or outpatient department. This cannot be attained until the present tendency more and more to exclude the practitioner from the hospital is reversed. Not least among Dr. Collings's contributions is his emphasis upon the fact that "the future of general practice is largely being determined without deliberate consideration of its problems. It is being determined mainly by the people responsible for hospital and specialist development, and in terms of compensation for recognised or half recognised, deficiencies instead of the correction of these deficiencies." No hospital or specialist service can compensate for a poor general-practitioner service: it will always be too late. It will be the better for medicine in England when this is recognised, and when any change contemplated in the organisation, the remuneration, or the development of other branches of the service is measured against the effect that change may have in enhancing or depressing the standards of general practice. This will best be done when general practice has its full representation on planning bodies at all levels: "With opportunity and encouragement, general practitioners could make a valuable contribution towards planning as well as operating the medical services.”

These paragraphs indicate but a few of the ways in which early action could be taken to make general practice a better service for our patients and a better life for ourselves and our successors—one which would attract and satisfy the good doctors we need. I realise I have said nothing new: there is little new to say. Long before Dr. Collings began to look at practice here, much thought and writing had gone to show the way to better practice conditions. The service Dr. Collings has done us is to shine his searchlight on to some deplorable conditions of practice, and to show how urgent it is for us to order things differently if we are not to perpetuate and extend this type of practice. The report must now be made a stimulus for action, and action must be based on a new policy, one which will lead to the rehabilitation of general practice. The Collings report may well be recognised in the future as a turning-point in the history of medicine in this country.

Bromley, Kent. A. TALBOT ROGERS.

“INTENSIVE” INTRAVENOUS ANTITOXIN TREATMENT OF DIPHTHERIA

SIR,—Your very reasonable review (March 18) of my new book *The Common Infectious Diseases* is appreciated; but when you take me to task for what you call a claim to “priority” in the “intensive” intravenous antitoxin treatment of diphtheria, I feel that some reply is desirable in the interests of historical accuracy.

In the preface I sought to explain the emphasis laid on certain subjects in my book by stating that in the last twenty years I had myself “advanced” certain new ideas, methods, and modifications of established practice. While the phraseology might have been more explicit I cannot see how this has become interpreted into a foolish claim for “priority.”

Your review mentions as an instance the “intensive” intravenous antitoxin treatment of diphtheria, and rightly names W. H. Park and V. Bie as pioneers. In the paper in *The Lancet* of July 7, 1928, in which, with a colleague, I “advanced” the idea of modifying existing practice in the treatment of hypertoxic diphtheria—namely, by employing large intravenous doses of antitoxin—I quoted freely from the work of Park and Bie. This paper was considered at the time to be so subversive of established practice that it formed the subject of leading articles in both *The Lancet* and the *British Medical Journal*. Thus, referring to my own as well as Bie's results, *The Lancet* stated (1928, ii, 22): “these results are so remarkable that they must lead to reconsideration of the current view that it is useless to give antidiphtheritic serum in doses of more than 30,000 to 50,000 units.” And the *British Medical Journal* (1928, ii, 453) stated: “this experience of the value of intravenous administration of antitoxin in large doses is, however, contrary to general opinion in this country as held by E. W. Goodall and others, and in America by W. H. Park, who have asserted that doses in excess of 30,000 and 50,000 units are useless.” Again, Dr. E. H. R. Harries, then of Birmingham, wrote in *The Lancet* of July 21, 1928, congratulating my colleague and myself upon our results and stating that, in comparable hypertoxic cases, our case-mortality was less than that in his series where large *intramuscular* doses of antitoxin had been mainly used.

However, not even W. H. Park in 1910, had “priority” in the treatment of diphtheria by intravenous antitoxin. One of my predecessors in Belvidere Hospital, Glasgow, Dr. D. L. Cairns, described in full 20 such cases in *The Lancet* of Dec. 20, 1902. But, as in many such instances, and owing perhaps to technical difficulties, the idea failed to gain acceptance then and on later occasions. Certainly in 1928, when my paper was published, the routine practice in the treatment of hypertoxic cases, except in Copenhagen, was to give antitoxin intramuscularly in doses which nowadays would be considered relatively small, and with results which, in my experience at Leicester at least, I recall with horror.

Park Hospital, London, S.E.13. H. STANLEY BANKS.

PUBLICITY

SIR,—A year ago a letter of mine, which you had published, was used by a national newspaper, without acknowledgment to *The Lancet*, in a way that made it seem that I had granted an interview. No redress was obtainable and no apology forthcoming.

Yesterday I attended, by invitation, a meeting of the Manchester Marriage Guidance Council, under the chairmanship of Dr. J. L. Burn, medical officer of health for Salford, of which the audience consisted of invited social and welfare workers. The meeting was addressed by Mr. A. J. Brayshaw, secretary of the National Marriage Guidance Council, on the subject of marriage guidance as a basic service to the community. I was not on the platform, but took part in the discussion, in which some 10 or 12 other speakers joined.

Today a national newspaper published an article in which I am wrongly described as a specialist in gynæcology. The names of the speaker and chairman, and the nature of the meeting, are not stated, and the impression is given that I gave a lecture on sex to this body. Some incorrect statements, and others which are distorted out of their context, are improperly attributed to me.

The risk of such publicity and distortion must inevitably prevent medical men from playing their part as citizens in this and many other spheres. I feel that the profession should be made aware of the dangers that modern journalism presents to free discussion.

Manchester. BERNARD SANDLER.

APPROACH TO THE UPPER THORACIC SYMPATHETIC GANGLIA

SIR,—In his letter of March 4 Mr. Haxton generously agrees that honour should be given where it is due; but, although he criticises Mr. Hedley Atkins's advice on the peraxillary route to the upper thoracic sympathetic ganglia, he does not seem to have read Mr. Atkins's description of the operation.[1] Mr. Haxton mentioned “painful convalescence inevitable to resection of rib”; but Mr. Atkins never mentioned resection of any rib in his description of the operation.

Until surgeons have decided whether sympathetic denervation of the hands is more thorough and more permanent after removing the stellate ganglion as well as the upper thoracic ganglia, or after prestellate ganglionectomy alone, the best method of approach seems difficult to decide. For it would appear that the anterior approach, as described by Gask and Paterson Ross[2] is the most satisfactory for stellate ganglionectomy, whilst the per-axillary route would appear to be the more direct approach if the second and third ganglia are to be removed without removal of the stellate ganglion.

The clear exposure of the third thoracic ganglion through the anterior approach on every occasion is a claim which I, like Mr. Atkins, think many surgeons would find difficult to substantiate. I agree that removal of the stellate ganglion through the axillary approach is apt to be a rather blind, and therefore a more dangerous procedure than the removal of this ganglion through the anterior approach.

If stellate ganglionectomy is required for sympathetic denervation of the upper limb, then the anterior approach

GENERAL PRACTICE TODAY

AN APPRECIATION

SIR,—It is a good military principle that after a reconnaisance has been made but before action is taken an appreciation shall be made of the situation. So although it is true that Dr. Collings, in concluding his illuminating report, does summarise his findings and gives his own individual recommendations for action, he will doubtless not begrudge one of that group whom he calls "the people most concerned—namely 'ordinary' general practitioners" the right to make an independent appreciation of his report and to suggest the action it might or should provoke.

My own first impression, which I find is shared by others, was that Dr. Collings's method of sampling must have thrown up a greater proportion of the bad than of the good in general practice in England, so that the picture it gave him was distorted. Then I realised that this was really unimportant. What mattered was that Dr. Collings had found practices existing in England of the bad types he describes; and had been able to observe the bad effect that working under such conditions had had on men who had come from their hospitals well trained, well qualified, and with good clinical disciplines. "The conditions and conduct of general practice in industrial areas make a mockery of our modern medical education and the disciplines and practices taught in our great hospitals." It is true that these practices Dr. Collings condemns existed before the coming of the National Health Service; it is equally true that the service has done nothing to abolish them and much to perpetuate and even to multiply their incidence.

If I read Dr. Collings aright, he believes that the industrial practitioner today is carrying too great a load, and often attempting to do this in insufficient premises, with poor equipment and inadequate ancillary help. He rarely has easy access to hospital diagnostic departments and even less often to hospital beds. In such circumstances, no matter how sincere his first intentions, it is fatally easy for him and his patients to come after a few years to accept a standard of hasty interview, spot diagnosis, and the transference of all cases of real responsibility to the care of the specialist services at the hospital as the best that general practice can offer.

At present it seems to be nobody's business to help him to do better work. The executive council attends only to the day-to-day administration of the service. It initiates nothing. It acts in no way as the protector of the general practitioner—neither by encouraging the local health authority towards health-centre provision, nor by discouraging the hospital management committees from abrogating the help their hospitals have so long had from the practitioner. As for the regional hospital boards "their attitude to the problems presented by industrial practice was one of resignation to the inevitability of that sort of thing, of hopelessness of doing anything about it at its source, and of consequent acceptance of the need to compensate for it through the agency of hospital and specialist services."

The bright thing about the Collings report is that Dr. Collings refuses to accept "the inevitability of that sort of thing" and believes that if the general-practitioner service is seen whole, and planned properly, there is scope for a much better service, and hope for the future, provided that "instead of continuing a policy of compensating for its deficiencies, we should admit them honestly and try to correct them at their source."

Chief among the deficiencies revealed as needing correction are ill-planned and ill-equipped practice premises; the heavy load of patients and lack of ancillaries which together rob the practitioner of time and opportunity to use his special skills; and the lack of opportunity for coöperation with colleagues in general or specialist practice. It is salutary to realise how many of these major deficiencies might have been alleviated if only we had been able to develop the health centre. Dr. Collings is well aware of this, and there is little doubt he is right in suggesting that the organisation of basic group practice units should be encouraged even in advance of any health-centre building programme. If such units could be helped to employ proper ancillary staff, and to coöperate better with hospital and local-authority services, the worst factors now depressing general practice might well be alleviated. And as money, materials, and labour do become available for building we should plan some inexpensive buildings in which these group-practice units could work, and so correct the present tendency to plan on the one hand elaborate expensive unattainable all-purpose health centres, or on the other, traditional buildings intended only for health-authority clinics.

Dr. Collings does not lay much stress upon the effects of our methods of payment of the doctors. He does not find any reason to believe that payment by capitation fee materially changes the doctor-patient relationship. Nevertheless, it must be recognised that payment made solely on a quantitative basis encourages the building of large practices and commensurately diminishes the time available for the investigation and treatment of each patient. Almost certainly we will have to find a way of reducing the handicap and hardship now borne by the man with the small list. Had the extra millions claimed by the General Medical Services Committee been available, their proposed increased capitation fee on the first [illegible] principal's list might have done much to make practice with smaller lists economically possible, and also to create more places for principals in practice. Even now a reconsideration of the distribution of the practitioners' fund is called for. It is, for instance, possible that by making the fixed annual payment (at its present or at an enhanced rate) a central and not a local charge something could still be done and done at once to help to introduce new doctors to areas most needing them, and to alleviate the problems of the areas where lists are never likely to grow large.

To all this must be added a closer association for the general practitioner with his local hospital, with ease of access to diagnostic departments, and greater opportunity to follow, discuss, and understand the investigation and treatment of his patient in hospital ward or outpatient department. This cannot be attained until the present tendency more and more to exclude the practitioner from the hospital is reversed. Not least among Dr. Collings's contributions is his emphasis upon the fact that "the future of general practice is largely being determined without deliberate consideration of its problems. It is being determined mainly by the people responsible for hospital and specialist development, and in terms of compensation for recognised or half recognised, deficiencies instead of the correction of these deficiencies." No hospital or specialist service can compensate for a poor general-practitioner service: it will always be too late. It will be the better for medicine in England when this is recognised, and when any change contemplated in the organisation, the remuneration, or the development of other branches of the service is measured against the effect that change may have in enhancing or depressing the standards of general practice. This will best be done when general practice has its full representation on planning bodies at all levels: "With opportunity and encouragement, general practitioners could make a valuable contribution towards planning as well as operating the medical services."

These paragraphs indicate but a few of the ways in which early action could be taken to make general practice a better service for our patients and a better life for ourselves and our successors—one which would attract and satisfy the good doctors we need. I realise I have said nothing new: there is little new to say. Long before Dr. Collings began to look at practice here, much thought and writing had gone to show the way to better practice conditions. The service Dr. Collings has done us is to shine his searchlight on to some deplorable conditions of practice, and to show how urgent it is for us to order things differently if we are not to perpetuate and extend this type of practice. The report must now be made a stimulus for action, and action must be based on a new policy, one which will lead to the rehabilitation of general practice. The Collings report may well be recognised in the future as a turning-point in the history of medicine in this country.

"INTENSIVE" INTRAVENOUS ANTITOXIN TREATMENT OF DIPHTHERIA

SIR,—Your very reasonable review (March 18) of my new book *The Common Infectious Diseases* is appreciated; but when you take me to task for what you call a claim to "priority" in the "intensive" intravenous antitoxin treatment of diphtheria, I feel that some reply is desirable in the interests of historical accuracy.

In the preface I sought to explain the emphasis laid on certain subjects in my book by stating that in the last twenty years I had myself "advanced" certain new ideas, methods, and modifications of established practice. While the phraseology might have been more explicit I cannot see how this has become interpreted into a foolish claim for "priority."

Your review mentions as an instance the "intensive" intravenous antitoxin treatment of diphtheria, and rightly names W. H. Park and V. Bie as pioneers. In the paper in *The Lancet* of July 7, 1928, in which, with a colleague, I "advanced" the idea of modifying existing practice in the treatment of hypertoxic diphtheria—namely, by employing large intravenous doses of antitoxin—I quoted freely from the work of Park and Bie. This paper was considered at the time to be so subversive of established practice that it formed the subject of leading articles in both *The Lancet* and the *British Medical Journal*. Thus, referring to my own as well as Bie's results, *The Lancet* stated (1928, ii, 22): "these results are so remarkable that they must lead to reconsideration of the current view that it is useless to give antidiphtheritic serum in doses of more than 30,000 to 50,000 units." And the *British Medical Journal* (1928, ii, 453) stated: "this experience of the value of intravenous administration of antitoxin in large doses is, however, contrary to general opinion in this country as held by E. W. Goodall and others, and in America by W. H. Park, who have asserted that doses in excess of 30,000 and 50,000 units are useless." Again, Dr. E. H. R. Harries, then of Birmingham, wrote in *The Lancet* of July 21, 1928, congratulating my colleague and myself upon our results and stating that, in comparable hypertoxic cases, our case-mortality was less than that in his series where large *intramuscular* doses of antitoxin had been mainly used.

However, not even W. H. Park in 1910, had "priority" in the treatment of diphtheria by intravenous antitoxin. One of my predecessors in Belvidere Hospital, Glasgow, Dr. D. L. Cairns, described in full 20 such cases in *The Lancet* of Dec. 20, 1902. But, as in many such instances, and owing perhaps to technical difficulties, the idea failed to gain acceptance then and on later occasions. Certainly in 1928, when my paper was published, the routine practice in the treatment of hypertoxic cases, except in Copenhagen, was to give antitoxin intramuscularly in doses which nowadays would be considered relatively small, and with results which, in my experience at Leicester at least, I recall with horror.

Park Hospital, London, S.E.13. H. STANLEY BANKS.

PUBLICITY

SIR,—A year ago a letter of mine, which you had published, was used by a national newspaper, without acknowledgment to *The Lancet*, in a way that made it seem that I had granted an interview. No redress was obtainable and no apology forthcoming.

Yesterday I attended, by invitation, a meeting of the Manchester Marriage Guidance Council, under the chairmanship of Dr. J. L. Burn, medical officer of health for Salford, of which the audience consisted of invited social and welfare workers. The meeting was addressed by Mr. A. J. Brayshaw, secretary of the National Marriage Guidance Council, on the subject of marriage guidance as a basic service to the community. I was not on the platform, but took part in the discussion, in which some 10 or 12 other speakers joined.

Today a national newspaper published an article in which I am wrongly described as a specialist in gynæcology. The names of the speaker and chairman, and the nature of the meeting, are not stated, and the impression is given that I gave a lecture on sex to this body. Some incorrect statements, and others which are distorted out of their context, are improperly attributed to me.

The risk of such publicity and distortion must inevitably prevent medical men from playing their part as citizens in this and many other spheres. I feel that the profession should be made aware of the dangers that modern journalism presents to free discussion.

Manchester. BERNARD SANDLER.

APPROACH TO THE UPPER THORACIC SYMPATHETIC GANGLIA

SIR,—In his letter of March 4 Mr. Haxton generously agrees that honour should be given where it is due; but, although he criticises Mr. Hedley Atkins's advice on the peraxillary route to the upper thoracic sympathetic ganglia, he does not seem to have read Mr. Atkins's description of the operation.[1] Mr. Haxton mentioned "painful convalescence inevitable to resection of rib": but Mr. Atkins never mentioned resection of any rib in his description of the operation.

Until surgeons have decided whether sympathetic denervation of the hands is more thorough and more permanent after removing the stellate ganglion as well as the upper thoracic ganglia, or after prestellate ganglionectomy alone, the best method of approach seems difficult to decide. For it would appear that the anterior approach, as described by Gask and Paterson Ross[2] is the most satisfactory for stellate ganglionectomy, whilst the per-axillary route would appear to be the more direct approach if the second and third ganglia are to be removed without removal of the stellate ganglion.

The clear exposure of the third thoracic ganglion through the anterior approach on every occasion is [illegible] claim which I, like Mr. Atkins, think many surg[illegible] would find difficult to substantiate. I agree that [illegible]oval of the stellate ganglion through the axillary *approach is apt to be a rather blind, and therefore a more dangerous,* procedure than the removal of *this ganglion through the* anterior approach.

If stellate ganglionectomy is *required for sympathetic* denervation of the upper *limb, then the anterior approach*

---

1. *Lancet*, 1949, ii, 1152.
2. Gask, G. E., Ross, J. [illegible] mpathetic Nervous System. London, 1

would seem to be the better of the two. If the stellate ganglion need not be removed, I believe that the second and third thoracic ganglia can be reached more easily, and seen more clearly, through the axillary approach than through the anterior one.

Leeds. MICHAEL C. OLDFIELD.

RELIEF OF PAIN IN RHEUMATOID ARTHRITIS WITH TETRAETHYLAMMONIUM BROMIDE

SIR,—In confirmation of Dr. Howell's experience with tetraethylammonium bromide in rheumatoid arthritis, described in your issue of Feb. 4 (p. 204), we should like you to publish this preliminary report.

Since November, 1949, we have tried tetraethylammonium bromide (T.E.A.B.) in chronic polyarthritis. Our reasoning has been as follows. Among the signs of rheumatoid arthritis there are some characteristic general reactions—for example, cold clammy hands and feet, atrophy of skin and muscles, decalcification of bones, and diffuse swelling of subcutaneous tissues. These reactions have much in common with the so-called functional vascular disorders and reflex dystrophies. The common feature of all seems to be vasomotor changes. Our working hypothesis is that these changes cause ischæmia, mainly in the joints and adjoining tissues, the ischæmia causes pain, and the pain immobilises the joints. This is a vicious circle, which vasodilatation should break; hence the temporary relief of pain by heat. The astoundingly quick relief that follows injections of deoxycortone combined with vitamin C may probably be explained in a similar way.

It seems an obvious step to try other vasodilator drugs, starting with T.E.A.B., which has already been tried in various vascular disorders.[1] This drug causes vasodilatation by blocking autonomic impulses.[2] Thus its effect may be compared with sympathectomy, which has been used in rheumatoid arthritis with a certain amount of success.[3]

Our material so far only amounts to seven thoroughly investigated cases, all with severe pain and reduced mobility in one or several joints. After 1–3 weeks' observation in hospital, to note any spontaneous improvement, we have started with a dose of about 5 ml. (0·5 g.) of T.E.A.B. ('Etamonin Astra') slowly injected, the blood-pressure being checked continuously. After this we have waited until the effect, if any, has disappeared. Then we have made a control injection of sterile water in the same way, to detect any possible effect of suggestion—in our experience a pitfall of the utmost importance. In some cases we have revised the doses, starting with a control injection and then continuing with T.E.A.B. When we have learnt the duration of the effect of the drug we have proceeded with a series of injections once or twice a day.

It is far too early to express an opinion on the eventual results of T.E.A.B. as treatment. In view of the theoretical considerations mentioned above, we first wanted to find out whether T.E.A.B. has any immediate effects such as we observed after combined injections of deoxycortone and vitamin C. Such effects have been observed in five of the seven cases, and three examples are given here.

CASE 1.—A female shop-assistant, aged 42, who has had chronic polyarthritis since the age of 13, leading to severe deformity of the right hip-joint and considerable deformity of the left knee and of the fingers. When trying to clench her right fist she could only get her finger-tips to 0·5–1 cm. from her palm. Two months ago she developed pain with reduced mobility in her right shoulder. After the injection of 7·5 ml. of T.E.A.B. relief began in 15 min. After 30 min. she had no pain, movements of the right shoulder were free, she could clench her right fist completely, and her formerly cold clammy hands were definitely warmer. After 4 hours she walked surprisingly easily and painlessly. Next morning she felt slight pain in her shoulder but no stiffness, and the stiffness has not reappeared during the following 3 months' observation.

CASE 2.—A sailor, aged 44, who has had several attacks of rheumatoid arthritis since the age of 30, but has no deformities. The present attack began in December, 1949, the main symptoms being swelling and stiffness of the left wrist. After the injection of 6 ml. of T.E.A.B. relief of pain began in 15 min. An hour afterwards the wrist was freely mobile with no pain. Compared with its condition before the injection, the mobility of the wrist had increased by 50°. The improvement slowly disappeared in the next 6 days. A further injection brought relief lasting about 10 days and a reduction in the swelling.

CASE 3.—A male clerk, aged 62, who has had rheumatoid arthritis since 1947, gradually getting worse but without deformities. His main symptoms were considerable pain, slight stiffness and swelling in all his fingers, and tenderness over the metatarsophalangeal joints. An hour after the injection of 5 ml. T.E.A.B. he had no pain, there was free mobility of the fingers, and walking was much easier. The duration of the relief was about 3 days. The same result followed a further injection, and the swelling then decreased.

To sum up, tetraethylammonium bromide has been tried in 7 cases of chronic polyarthritis. In 2 there was no effect, but in 5 there has been relief of pain and increased mobility, starting 15–30 minutes after the injection. This may be compared with the effect we have seen after combined injections of deoxycortone and vitamin C. We presume that the effect is caused by changes in vasomotor tone in the joints and adjoining tissues. We have as yet no opinion on the question whether T.E.A.B. can be used for treatment.

THE CARNAGE ON THE ROADS

SIR,—Dr. Learoyd's excellent article of Feb. 25 does not mention some important points, of which perhaps the strangest is the apparent lack of interest shown by the medical profession. Beyond occasional complaints from the provinces that hospitals are filled with road-accident cases, or from West End consultants that their progress has been hindered by foolish pedestrians, the medical press has carried little comment. Perhaps, like the magistrates, the doctors are often keen motorists.

Another inexplicable feature is that as a rule no proper inquiry is held into causes—in striking contrast to the long and searching investigation into rail and air accidents.

Finally, road-safety measures have had to compete for many years with what can only be described as an "anti-safety" campaign carried out by the motoring interests, who have preached the dangerous doctrine that "speed is not a cause of accidents." Whatever grain of truth there may be in this statement when applied to experts driving high-class machines, it is surely, to put it mildly, a little rash to proclaim it to all and sundry on roads that have to carry mixed traffic of all descriptions. As well as opposing tests for drivers, the motoring interests have strenuously resisted restrictions, such as speed limits and pedestrian crossings, and they have cultivated the legend of "police persecution" while fostering resentment of any discipline or control. So many excuses and justifications, apart from bad driving, have been put forward, that accident production may have been actively encouraged.

Dr. Learoyd mentioned the Royal Society for the Prevention of Accidents. May I suggest that medical men may make a positive contribution at trivial cost by joining the Pedestrians Association?

RESEARCH ON ARTHRITIS TREATMENT

SIR,—The concentration in your journal of the lively liscussion about Lewin and Wassén's results with heumatoid arthritis[1] encourages me to record a case vhich might help to prolong the salutary confusion which eigns at present on the question of the action of ascorbic acid in arthritis.

An unmarried woman, aged 43, somewhat obese but in good health, who, although she has had occasional "rheumatic" twinges, does not suffer from any definite joint affection, slipped early in June, 1948, and twisted her left ankle. There was considerable swelling and pain below the external malleolus, and as the swelling had not subsided after ten days she consulted a surgical outpatient department. On examination, movement was found to be free and painless except on extreme inversion. There was swelling over the lateral malleolus and pain on pressure over the lateral ligament. X-ray examination of the ankle did not show any bony injury. A tear of the lateral ligament was diagnosed and adhesive strapping applied; two weeks later the ankle had returned to normal and remained so for the ensuing two years.

On Sept. 21, 1949, in the course of an investigation into the action of high doses of vitamin C, she started to take 300 mg. of ascorbic acid (Crookes) daily. After twenty-three days, having taken 16 such daily doses (4·8 g.), she stopped taking the drug because she had developed a slight swelling of the right ankle and considerable swelling and stiffness of the left ankle with prominence of the superficial veins over the left external malleolus. Within a few days of the cessation of treatment both pain and swelling had disappeared and the ankle had returned to normal. Six weeks later, in November, 1949, she resumed the same daily dose of ascorbic acid. After five days, some stiffness was felt in the left ankle but treatment was continued. After fifteen days, swelling, discomfort, and venous engorgement of the left ankle again developed to such a degree that the drug had to be stopped. The right ankle was not affected on this occasion. The total amount administered was 4·35 g. Seven days after cessation of vitamin-C intake, the ankle had again returned to normal.

On Feb. 3, 1950, she resumed once more the consumption of 300 mg. of ascorbic acid daily. Five days later some twinges were felt in the left ankle but she continued treatment. On the 16th day the ankle felt stiff and there was pronounced puffiness under the left external malleolus. On the 20th day, some pain was added to these complaints. The ankle continued in this condition until the 24th day, when treatment was stopped. The total amount of drug until the development of œdema was 4·2 g. The total amount until the cessation of the experiment was 6·6 g. The ankle continued puffy and stiff for another week and then returned to normal.

It is important to note that recovery from the original accident had been so complete that the patient was quite unable to remember which side had been involved, so that it was necessary to consult the hospital records to ascertain that it had been the left side. Apart from her moderate obesity there are no grounds for suspecting any upset of steroid metabolism. Her blood-pressure is 145/70 mm. Hg.

The first point—worthy of record because not previously recorded—is that vitamin C in high dosage may awaken a dormant periarthritis. None of the other seven volunteers in this investigation have so far shown this effect although most of them have received similar doses for a much longer time; but this is a small series and reports of prolonged administration of vitamin C in such high dosage are very scanty. The next point exciting attention is the extraordinary memory displayed by the patient's left ankle. It is an example of the fact that complete structural, and even functional, restoration is not always synonymous with a restitutio ad integrum of local metabolism. This also serves as a timely reminder that a morbid alteration of local reactivity is probably as important and integral a part of connective-tissue disease as the possible upsets in systemic factors which has recently received so much well-merited attention.

It was shown by Selye[2] that deoxycortone acetate can aggravate experimental arthritis, and it would seem that the beneficial effect demonstrated by Lewin and Wassén is produced by the synergistic action of two substances, each of which can aggravate arthritis, under certain conditions, when acting singly. This case also tends to throw some slight doubt on the belief that oxydation of adrenal steroids is a complete explanation of the effect of ascorbic acid in rheumatic disorders.[3]

Two further apparent paradoxes in this field may be mentioned. One is the case of Zierler and Lilienthal,[4] who found that administration of deoxycortone acetate in a subject with myotonic dystrophy led to increased sodium and water excretion. The other comes from Walter's[5] description of scurvy in its severest forms:

> "But a most extraordinary circumstance, and what would be scarcely credible upon any single evidence, is, that the scars of wounds which had been for many years healed were forced open again by this virulent distemper. Of this there was a remarkable instance in one of the invalids on board the Centurion, who had been wounded above fifty years before at the battle of the Boyne, for though he was cured soon after, and had continued well for a great number of years past, yet on his being attacked by the scurvy, his wounds, in the progress of his disease, broke out afresh, and appeared as if they had never been healed."

As a student of vitamin-C action, I have no hesitation in accepting this account as accurate, and it would therefore seem that an extreme lack of vitamin C, as well as an excess of this substance, can, under certain conditions, reactivate old injuries.

It would be easy, Sir, to discount all these contradictions (to which we might add the divergent findings of those who have repeated Lewin and Wassén's therapeutic trials) by supposing the periarthritis in my case to be due to coincidence, by disallowing the findings of Zierler and Lilienthal as not being adequately controlled, and by refusing to accept the testimony of an 18th-century lay observer. I prefer to see in these paradoxical phenomena the tantalising evidence of some elusive truth which we shall only capture if we do not allow our views to become prematurely settled.

I should like to conclude this letter by expressing my gratitude to the patient mentioned here, who, although a keen dancer, has allowed herself three times to be the subject of an unpleasant and somewhat frightening disability.

Gerontological Research Unit,
Usher Institute, Edinburgh.

ERICH GEIRINGER.

SIR,—In my letter of Jan. 21, I mentioned my experiences of the method of Lewin and Wassén[6] with deoxycortone acetate and ascorbic acid in rheumatoid arthritis. Instead of deoxycortone I have used with similar success testosterone (25 mg.), progesterone (4 mg.), and also œstrone (5 mg.).

Presuming that the action on the sterones is due to the redox power of ascorbic acid, I have tested other redox substances, such as methylene-blue and sodium thiosulphate. Following an intramuscular injection of a sterone I injected intramuscularly or intravenously 10 ml. of a 10% solution of methylene-blue. In cases which had responded well to the technique of Lewin and Wassén, the injection of a sterone (intramuscularly) with subsequent injection of methylene-blue intravenously or intramuscularly produced similar good results, though perhaps not so promptly as with ascorbic acid. However, 10 ml. of a 10% solution of sodium thiosulphate, injected intravenously 3–5 minutes after intramuscular injection of a sterone, acts better than, and also as promptly as, ascorbic acid. Sodium thiosulphate is cheaper, and is free from the side-effects caused by methylene-blue.

---

1. Lewin, E., Wassén, E. *Lancet*, 1949, ii, 993.
2. Selye, H. *Brit. med. J.* 1949, ii, 1129.
3. Hallberg, L. *Lancet*, Feb. 25, p. 351.
4. Zierler, K. L., Lilienthal, J. L. jun. *Amer. J. Med.* 1948, 4, 186.
5. Anson's Voyage Round the World. London, 1947.
6. Lewin, E., Wassén, E. *Lancet*, 1949, ii, 993.

I believe that this mysterious alteration of deoxycortone and other sterones into a "cortisone-like" substance is caused, not by simple oxidation,[7] but by the redox action of such substances as thiosulphate and methylene-blue.

In further investigations I have also tried combined intravenous injections of 10 ml. of a 10% solution of sodium salicylate together with 10 ml. of a 10% solution of sodium thiosulphate. With this injection *without* a sterone I have obtained better analgesic results than by injection of sodium salicylate alone (without thiosulphate).

It seems possible that the well-known antirheumatic action of sulphur compounds may be connected with their redox power.

Lodz, Poland. MARCELI LANDSBERG.

SIR,—In a search for steroids which do not have the untoward effects of deoxycortone, it seemed justifiable to assess the value of 21-acetoxypregnenolone, which is structurally related to deoxycortone acetate and has a very slight mineral-corticoid activity.

We gave 21-acetoxypregnenolone intramuscularly in doses of 5–20 mg., followed by 1 g. of ascorbic acid intravenously, in 15 cases of chronic joint disease, including some of rheumatoid arthritis. The therapeutic effect was comparable to that obtained with deoxycortone acetate and ascorbic acid.

When we used deoxycortone and acetoxypregnenolone in 40 cases of osteoarthritis, we obtained a more satisfactory improvement than in strictly inflammatory processes; in fact, in a series of 12 cases of rheumatoid arthritis, all in the active phase, some advanced and some early, we did not obtain results as definite as did Lewin and Wassén.

21-acetoxypregnenolone, though no more effective than deoxycortone, allows more prolonged treatment and avoids the hazards of deoxycortone.

FLUID STANDARDS

SIR,—Your note of March 18 (p. 522) on Standardising Spoons implies that the American ounce is $^1/_{16}$ of an Imperial pint. This may be true for cookery, but in infant feeding and measuring petrol for cars, surely the essential point is that there are only 16 ounces (each roughly similar to our ounce) in the American pint. Mitchell-Nelson [8] gives:

1 fl. oz. = 29·5737 c.cm.; 16 fl. oz. = 1 pint = 473·179 c.cm.

This may be contrasted with Hutchison and Hunter [9]:

1 fl. oz. = 28·39 c.cm.; 20 fl. oz. = 1 pint = 567·9 c.cm.

or the L.C.C. *Pharmacopœia* (1936):

1 fl. oz. = 28·41 c.cm.; 1 pint = 568·25 c.cm.

or the Great Ormond Street *Pharmacopœia* (1933):

1 fl. oz. = 28·42 c.cm.; 1 pint = 568·24 c.cm.

Black's Medical Dictionary (1941) also gives:

1 fl. oz. = 28·42 c.cm.

Would you please, Sir, tell us the number of millilitres (to four places of decimals) in our ounce?

Guy's Hospital,
London, S.E.1. RONALD MAC KEITH.

*** According to the *B.P.*, 1 pint = 568·25 ml. So the fluid ounce = 28·4125 ml. In future it is proposed that the medicine tablespoon should contain $^1/_{40}$ of a pint—i.e., 14·2062 ml.—whereas the cookery tablespoon will contain $^1/_{32}$ of a pint, or 17·75 ml.—ED. L.

STERILISATION OF SYRINGES

SIR,—The satisfactory sterilisation of syringes which are in constant use by the anæsthetist during a busy operating-theatre session has been a source of worry to me for many years, especially since the appearance of a fresh hazard in intravenous work—the hepatitis virus.

In many hospitals it is still customary for the syringes used for thiopentone, curare, &c., simply to be rinsed in doubtfully sterile water after use and put back into definitely non-sterile spirit. The sediment at the bottom of the spirit-containing vessel is sometimes so thick as to bring to mind the Ancient Mariner's "ribbed sea sand," and the variety of organisms that can often be cultured from this deposit is truly astonishing. Hitherto there have been only two satisfactory alternatives to this uncleanly method. (1) The use of a large number of syringes boiled or, better, autoclaved for each session; this is both cumbersome and, in the case of 'Record' syringes, destructive. (2) Boiling up a lesser number of syringes in relays during the session; this method involves frequent delays while waiting for a fresh syringe and the syringe mortality is apt to be high.

For many years I have used oil sterilisation, at home, of the syringes for my private equipment, and this has led me to try to design a portable, easily worked, electric oil-sterilising unit. This method of sterilising does not seem to be sufficiently well known or its merits appreciated. It is well described in M.R.C. *War Memo. no. 6*, 1942: "To sterilise a record type of syringe . . . oil at a temperature of 120–130°C is rapidly drawn into the syringe . . . the syringe should be removed from the oil and inverted so that the oil reaches every part of the inside of the syringe. The oil is then expelled and the process repeated two or three times. . . . The syringe is now ready for use."

Needles are easily sterilised by placing them in the oil-bath for $^1/_2$–1 minute and removing them with forceps. It must of course be appreciated that, though the needle is entirely sterilised, the syringe is only sterile on the inside. This is of little consequence, since only the needle (which is affixed with forceps) penetrates the patient's tissues.

It is well to rinse the syringe with water before sterilising, not only to wash out any blood but also because presumably the layer of superheated steam that forms between the oil and the inside of the syringe is the most effective sterilising factor.

The apparatus described here is small and easily portable and can be set up in a moment on a convenient corner of the trolley. It takes only 2 or 3 minutes to reach the necessary temperature and is thermostatically controlled to maintain the required temperature range. After a syringe has been sterilised, the temperature may drop below 120°C for a few seconds, but it almost immediately rises again and the apparatus is ready for the next syringe. A thermometer is incorporated to check the operating temperatures and thus ensure that the apparatus is working properly.

THERMOMETER BENT TO FIT INSIDE CONTAINER
OIL
ELECTRICAL HEATING ELEMENT
TO MAINS
THERMOSTATIC CONTROL

---

[7] Hallberg, L. *Ibid*, Feb. 25, p. 351.
[8] Mitchell-Nelson's Textbook of Pediatrics. Philadelphia, 1946.
[9] Hutchison, R., Hunter, D. Clinical Methods. London, 1949.

I have made a series of tests with this method, which show its high degree of efficiency. Two syringes (marked A and B) were used for each test to provide a double check. The results were as follows:

Nature of test	*Temperature of apparatus* (°C)	*Syringe A*	*Syringe B*
After sterilisation of clean syringe	120	Sterile	Sterile
After contamination with 1/50 concentration of 4 hr. living broth culture of *Staph. aureus*	130	Sterile	Sterile
After contamination with 1/1000 week-old sporing culture of *B. subtilis*	120	Sterile	Sterile
After massive contamination with *B. subtilis* spores	130	Slight growth only after a week	Sterile

Boiling for 20 minutes is required to kill non-sporing pathogenic organisms. Viruses are killed by 5 minutes' boiling. It thus seems safe to assume that the oil method is certain to eliminate the latter. Sporing organisms need 90 minutes' boiling, 15 minutes' autoclaving at 15 lb. pressure, or 1 hour of dry heat at 160°C. Thus for practical theatre purposes, in my opinion, the advantages of the oil method of sterilisation are unquestioned.

My thanks are cordially extended to Mr. S. N. Bowden, senior technician at the Memorial Hospital, Woolwich, for his help. The apparatus was made for me by Medical Industrial Equipment Ltd., and I am grateful to Mr. E. P. Childerhouse, their director, for his advice on the execution of the design.

Woldingham, Surrey. F. BARNETT MALLINSON.

CORTISONE AND A.C.T.H.

SIR,—May I point out that the statement, in your annotation of March 18, that the article by Dr. Long and Dr. Miles, in the same issue, is "notable for containing the first report on work carried out in Britain with cortisone," is not correct.

As long ago as February, 1947, a paper on the effect of 'Cortisone' on lactation in adrenalectomised rats was published from this institute.[1]

The National Institute for Research in Dairying,
Shinfield, near Reading.
S. J. FOLLEY.

DANGER FROM THE NEWER INSECTICIDES

SIR,—Having read your annotation of March 4, I am concerned in particular at the statement you make, "but in the field the difficulties in ensuring adequate protection for individual workmen are almost insurmountable." All the evidence to date, both in this country and in the U.S.A., shows this statement to be incorrect.

I enclose a copy of a leaflet we are sending out to all people on our circularising lists, and which will also be attached, together with the instruction label, to all containers of 'Parathion' preparations which we send out. I would also draw your attention to an article in the *Grower* (March 11, p. 470) depicting the protective clothing which should be worn.

Intelligently used, parathion is a remarkably effective insecticide, and if the manufacturer's instructions are carried out, it can be used with safety. It is very regrettable that there has been so much loose writing in the daily press. This has caused great concern amongst fruit-growers.

I would point out also that, in this country, wettable powders containing parathion are not used at all. The two firms handling most of the parathion in this country are ourselves and Messrs. Plant Protection: one or two other firms are handling it, but to a very much smaller extent. Our material is being sold as a miscible-type preparation containing 20% of parathion (I believe there is only one preparation with a higher content), and there is therefore no need whatsoever to wear respirators in the field.

G. L. HEY
Wheathampstead, St. Albans, Herts.
Senior Entomologist, The Murphy Chemical Co. Ltd.

⁂ The accidents in the United States among men handling parathion in the factory and in the field make us believe that this insecticide is far more dangerous than any used in the past (e.g., nicotine or lead arsenate). The mode of action of the organic phosphorus compounds is entirely different; the onset of symptoms is insidious, and deaths have occurred despite care in handling. We understand that at least six firms are distributing parathion and similar substances in Great Britain, and that farmers complain of the unsuitable containers in which parathion is sometimes supplied. Effective protection of the worker is cumbersome and costly, and we fear that the proper clothing and appliances will not always be used when necessary.—ED. L.

ADMISSIONS TO HOSPITAL

SIR,—I was interested to read (March 18, p. 518) that Bradford (B) hospital group have a doctor undertaking home visits to assess the comparative medical urgency of chronic sick cases on the waiting-list for admission.

In York this work is undertaken by the medical officer of health and welfare officer. This arrangement provides a valuable link with the hospital management committee; it also enables the local authority to arrange for domiciliary services without delay, and helps this authority to assess the extent of the need for "Part III" accommodation. May I recommend this for consideration as an alternative to the Bradford procedure?

C. B. CRANE
York. Medical Officer of Health.

PENICILLIN

SIR,—As a parent who has just seen, once again, the effect of penicillin on a sick child, may I put on record the immense gratitude that one feels to all those known and unknown chemists who have made this miracle possible? And not only to these but to the whole medical profession who, directly and indirectly, do so much in guarding our happiness.

It seems such a long way from the nursery to the medical school and the laboratory that gratitude tends to become inarticulate; but nevertheless it is very deeply felt by a great number of people, including myself.

Bridport, Dorset. ELIZABETH LISTER.

ERGONOMICS RESEARCH SOCIETY

SIR,—In July, 1949, a group of people decided to form a new society for which the name the "Ergonomics Research Society" has now been adopted. Ergonomics by definition is to mean "the study of the relation between man and his working environment," particularly the application of anatomical, physiological, and psychological knowledge to the problems arising therefrom. This covers the field which has variously been described as "fitting the machine to the man," human engineering, that part of industrial psychology not concerned with vocational guidance, &c.

The society is intended to bring together workers in the fields of applied psychology, physiology and anatomy, and movement study. Two scientific meetings have already been held, at the second of which the rules for the society were adopted. They lay down that ordinary members shall be research-workers in the above fields and that others interested may become associate members. Meetings will be held three or four times a year,

---

1. Cowie, A. T., Folley, S. J. *J. Endocrinol.* 1947, 5, 24.

at which papers will be read, demonstrations given, and business transacted. It is hoped to publish papers presented to the society.

Anyone interested in the activities of the society is invited to write for further information to the secretaries, at Sussex House, 34, Palace Road, East Molesey, Surrey.

Obituary

ALFRED HENRY PROCTOR

M.D., M.S. DURH., F.R.C.S.E.

Colonel A. H. Proctor, emeritus dean of the British Postgraduate Medical School, died at Hexham, Northumberland, on March 23.

Alfred Henry Proctor was educated at Rutherford College and the University of Durham. He interrupted his studies to serve in the South African war, and this delayed until 1902 his qualification as M.B. In 1904 he graduated M.S., and in 1905 M.D. with gold medal.

In 1904 he entered the Indian Medical Service. In the first world war he served in France, Egypt, and Mesopotamia; he was twice mentioned in despatches and in 1917 was appointed D.S.O. In India he was successively surgeon at the Medical College Hospital, Calcutta, and surgeon and (from 1923 to 1933) surgeon-superintendent of the Presidency General Hospital, Calcutta. In 1933 he was appointed surgeon-general to the government of Bengal; and from 1933 to 1935 he served as inspector-general of civil hospitals, United Provinces. He was honorary surgeon to the Viceroy.

On returning to this country in 1935, Colonel Proctor became dean of the British Postgraduate Medical School (now the Postgraduate Medical School of London); and he served in this capacity until 1944, when he retired at the age of 65. Thereafter he was medical superintendent of the Southport E.M.S. Hospital until 1948 when he went to live in his native Northumberland.

G. G. T. writes: "Proctor was always a good student and an outstanding man whom all respected and admired for his absolute integrity and stern sense of duty. Although a great many important administrative posts fell to his lot he was always a clinician and a very competent surgeon. When on leave from the I.M.S. he spent quite a lot of time visiting his old hospital at Newcastle-upon-Tyne, and in one of these interludes he did some postgraduate work in Edinburgh and became a fellow of that college. That was in 1923.

"As surgeon-superintendent of the Presidency Hospital in Calcutta he did quite a lot of surgery and acquired a high reputation for his work among the community. He was also inclinable to research and was very fond of the microscope.

"As dean of the Postgraduate Medical School he was a notable success. His calm deliberate manner, his obvious sincerity, his helpfulness to juniors, and his powers of conciliation were all assets of great value in the early stages of that venture. His subordinate staff and the technicians were devoted to him and recognised his absolute fairness. Proctor was also a soldier and understood what discipline meant, but he never tried to impose conditions on others that he would not himself observe. He was good at finance and very rigid about the use of public funds, of which he took as much or more care than if it had been his own money.

"He had great ideas about postgraduate education. He recognised the need for education of specialists but never forgot the claims of general practitioners and always stood out for their interests. Before the war he went to Germany to investigate the conditions of postgraduate education and to explain the objects and efforts of the Postgraduate School. When the war came along he lived in the hospital for a good part of that time, and he took a hand in the clinical work as well as in Home Guard duties.

"At the B.M.A. he did good work on the naval and military committee, which later became the Armed Forces committee; and almost to the time of his death he was a member of the Central Medical War Committee.

"His principal recreation was fishing, and he loved to steal away to some of the streams in Northumberland or to throw a line among the salmon in Aberdeenshire. He was the most loyal and truest of friends."

O. E. N. writes: "Colonel Proctor came to the Postgraduate School after a distinguished career in the I.M.S.—so distinguished that it only just missed the very highest level. The school had hardly started, and there was the whole of the administration to be organised; the qualities which Colonel Proctor brought were just what the school needed. He had a wonderful experience on which to draw: he had run hospitals himself, and had inspected the running of hospitals by others; he had been a professor of surgery, commanded in the field, held the responsibility for providing harassed ministers with the answers to questions, engaged in private practice. People found it difficult to accept that he had had so much experience; it was easier to imagine that he was just a soldier, who did not understand academic and medical matters.

"Coming to the first medical school to be associated with a L.C.C. hospital, he appreciated the difficulties and problems of both sides, and the trust he inspired in municipal administrators helped greatly the cooperation of two bodies which might have been mutually suspicious. He had no difficulty in building up the administrative organisation of the school; it came easily to him. He had to put up with a good deal of needless interference from the bright little notions of bright little people, who did not understand that he had faced those particular problems thirty years before, and had not only worked out the answers long ago but had had almost a life-time of experience of the practical effects of different systems. Fortunately for himself, Colonel Proctor was not one of those who dismiss from their minds all the details of a solved problem; he had no difficulty in marshalling the arguments all over again. He had, in any case, a habit of preparing for anything that might crop up in a discussion with great care and elaboration. He had all the facts collected, but he was so careful never to make the least slip that he would often refrain from producing the appropriate argument in debate, but would hunt among his papers for what he knew was there and would fail to find it in time. He was, himself, deliberate and slow-moving, and he refused to be hurried, either by the quick and superficial or by the quick and brilliant.

"He had been brought up in a very rigid puritanical sect, and the training left a stamp on him for life. To him the supreme authority was the 'stern daughter of the voice of God,' and the highest power an equally stern fate. Life to him was a hard thing and in his outlook he was essentially a stoic. (His face would have done well for a Roman philosopher.) But underneath a firm exterior he was much more 'tender' than 'tough' in James's sense. Indeed, it was one of his difficulties that he, one of the tender, was always in positions which would have been easy for the tough. He never blamed: he pitied. He was inwardly shocked by such things as the willingness of a doctor to accept a contract in the E.M.S. which involved liability to be sent elsewhere, so long as he was left where he was, knowing that as soon as he was asked to fulfil his part of the contract he could (and would) resign. But Colonel Proctor had seen so much of that sort of thing that he accepted it as a most unfortunate fact, and the calmness which accompanied his acceptance was mistaken by those who knew him least as cynicism.

"He demanded an almost impossibly high standard from himself, and wished he could expect the same of others. He was by nature very gentle and conscious of the susceptibilities of others; duty often prevented his showing it. Very high moral standards are not popular; we tend to be made to feel inferior in their presence; it may have been this which contributed to make Colonel Proctor 'unlucky.' Schemes dear to his heart tended not to come off; persons were liable to be antagonised;

he seemed just not to achieve the highest posts for which he was eligible. Life was never just 'fun' to him, as it was to others less worthy. But it is to be suspected that he did better than succeed.

"He was a gentleman if ever there was one; there was no better chief to work for; he had many very sincere friends. And he could, if he had let himself, look back on a large life, with many things done, no man injured, and many things seen and endured."

Colonel Proctor is survived by his wife and two sons.

ARTHUR HENRY EVANS

O.B.E., M.D., M.S. LOND., F.R.C.S.

Mr. Arthur Evans, consulting surgeon to Westminster Hospital, died on March 20 in his 79th year.

His long and distinguished association with the hospital extended over 60 years; for he entered as a student with a scholarship in 1890 when, as he recalled with amusement, the premedical and preclinical subjects were taught by any members of the staff who claimed or were saddled with authority and responsibility. This teaching was supplemented by outside help, and Evans learnt biology for the London University preliminary scientific examination from the future celebrity H. G. Wells. He qualified in 1895, and after holding all the resident appointments then available he passed the M.B. Lond. with honours in 1897. The same year he took the F.R.C.S., and the following year he proceeded to the M.D.

Thus experienced and equipped, his future career was not easily decided. "I never had, and never wish to have, a better house-surgeon," said Charles Stonham, a man of rare discrimination and rarer praise, an opinion which determined his choice when in 1900 at the beginning of the South African War he asked Evans, who was already established in Liverpool, to join him as his assistant in the Imperial Yeomanry Hospital. For his services abroad Evans was mentioned in despatches.

On his return to England in 1901, he passed the M.S. Lond. and the following year he was elected to the staff of Westminster Hospital—the first Westminster student to gain that distinction. At the same time he held the appointment of demonstrator of anatomy and physiology and later of pathology, teacher of surgical anatomy, operative surgery, and general surgery, and of surgeon to the Seamen's Hospital. He was also senior surgeon to the London Temperance, to Bethlem Royal, and to the Royal Masonic Hospitals.

Evans was so versatile that it is difficult to identify not one branch upon which he has left his mark, but one in which he has not been conspicuous. At first the influence of Robert Jones in Liverpool attracted him towards orthopædics. Later, circumstances drew him to the specialty of otology and laryngology and he established an intimate contact with the leading performers on the concert platform and in opera. In this sphere his reputation and popularity were outstanding; for, apart from his professional skill, his personality, his musical ability, and his knowledge of dramatic technicalities, all combined to a sympathetic understanding of the doubts and difficulties of the artistic temperament. But to a man of his attainments the comparative superficiality of such a career, however attractive, became distasteful, and he turned to what he regarded as the more serious business of life. He was a pioneer in thoracic surgery at the Royal Chest Hospital, his work on the gall-bladder and thyroid laid foundations the value of which have been gratefully acknowledged by his pupils who have acquired distinction in these departments: and that the taught should have eclipsed the teacher was to him a supreme satisfaction.

In the 1914–18 war he looked after the wounded at Westminster, the Royal Masonic, the Royal Chest, and the 4th London General Hospitals and at Aldford House Park Lane Hospital for Officers. He also acted in an advisory capacity at the War Office as inspector of surgical instruments. For this work he was later appointed O.B.E. After a term of office as senior surgeon to Westminster Hospital, in 1937 he was appointed consulting surgeon.

Evans contributed little to medical literature. Writing he found laborious. As a clinical teacher he was brilliant. Knowledge and wisdom were accompanied by pertinent anecdote, and a lecture or ward round was both entertainment and instruction. His Hunterian lecture on the Surgery of the Gall-bladder (1929) was enriched by the demonstration of a magnificent collection of specimens from his own operations. With Sir James Purves-Stewart, his corresponding senior physician at Westminster, he wrote *Nerve Injuries and Their Treatment* (1916), and his article on A Rubber Œsophagus in the *British Journal of Surgery* (1933) is a classical exposition of surgical enterprise and skill.

It is easier to enumerate the milestones in a man's career than to write of the traveller himself. But something must be said of a man with an unforgettable personality. Arthur Evans had an irrepressible joie-de-vivre which triumphed over all vicissitudes and compelled a like optimism in all with whom he came in contact. He was a brilliant natural comedian. An after-dinner speech delivered without premeditation was an inexhaustible stream of wit and ready repartee. Even his casual conversation scintillated. Yet when occasion demanded he could be serious enough but never solemn. He had a capacity, amounting to genius, for imparting bad news with a gentleness which softened the hardest blow. He could answer the question "is it cancer?" with no evasion of the truth yet with an interpretation that sent the inquirer away comforted. His faults were the defects of his qualities. In expressing his opinion of somebody's worth or suitability, innate kindliness and Celtic exuberance led to over-generous assessment, while any depreciation was almost absurdly attenuated. His praise was always without qualification; his dispraise never. And so with his one foible. Early in life he was so impressed with the evils of intemperance that he was unable to entertain anything but an inflexible insistence upon total abstinence. But all other human weaknesses he accepted not only with forbearance but with compassion and sympathy.

His last years were clouded by progressive parkinsonism. Yet crippled and handicapped in all activities he remained cheerful and uncomplaining, retaining to the end his mental vigour, his affection in his old medical school, and interest in all its doings.

He is survived by a widow, a daughter, and three sons, two of whom are surgeons, one on the staff of Westminster Hospital.

A. A.

SIDNEY VERE PEARSON

M.A., M.D. CAMB., M.R.C.P.

Dr. S. Vere Pearson, for many years physician to Mundesley Sanatorium in Norfolk, was an outstanding example of a doctor who had graduated into his specialty through personal experience of disease. One of the recognised authorities on the sanatorium treatment of tuberculosis, he was himself an example of cure by rest, fresh air, and graduated exercise.

He came from a large Nonconformist family. His father, the Rev. S. Pearson, had married Miss Bertha Crosfield of Liverpool, and their large and able family achieved distinction in many ways. One of Pearson's brothers became a missionary in India and was a close friend of Rabindranath Tagore, another became headmaster of Tettenhall College, and a third is a member of the well-known firm of hospital architects who built Midhurst and much of Mundesley Sanatorium.

From Manchester Grammar School Pearson went to Emmanuel College, Cambridge, where he took his B.A. in 1896. He continued his medical studies at St. George's Hospital, but he returned to Cambridge for a short period in his first year at the hospital to row in his university boat. He always kept his enthusiasm for rowing and for some years after the 1914–18 war he went up to Emmanuel each year to help coach the college crews.

Shortly after qualifying in 1900 he held resident appointments at the East London Hospital for Children at Shadwell in the East End. He had just completed this appointment when, as he himself described it, "a house-physician at St. George's with five months of his term of office to run contracted typhoid, and I stepped into his shoes." Six months as house-officer at the Brompton followed. Encouraged by his appointment as senior medical registrar at St. George's, he decided to settle in consultant practice in London: He was appointed to the staff at Shadwell, and everyone thought he would get the next staff appointment at St. George's, when an unexpected hæmoptysis changed all his plans. Within a few weeks he had set out for Nordrach in the Black Forest, where he was one of Walther's earliest patients. After six months abroad a hurried visit to London confirmed his decision not to return to consulting practice there, and he decided to become a sanatorium physician; for though at that time there were few such posts in England, he felt "their day was dawning." Accordingly he went back to Nordrach to complete his cure and his education. In 1905 he was offered the post of medical superintendent at Mundesley in succession to Dr. Noel Bardswell. When he started work he was still a sick man and liable to bouts of fever and hæmoptysis. Those who only knew him in later life as a man of exceptional vigour found it hard to realise that the inconvenient closeness of the doctors' houses to the sanatorium was due to his inability in his early years there to rely on being able to walk more than 100 yards.

When Pearson went to Mundesley it was a sanatorium built on the conventional chalet plan of the late 19th century. Under his management it grew into a modern sanatorium-hospital with all essential requisites. In the treatment of pulmonary tuberculosis in this country his name will always be linked with the introduction of artificial pneumothorax, an innovation he carried out in 1910 in association with Claude Lillingston and A. de W. Snowden. Although without X-ray control, the new method steadily overcame opposition, eventually proving to be one of the major therapeutic advances of the century. Throughout his life he was receptive of new ideas, and in the daily medical conferences at Mundesley it was the rule for the youngest to speak first on each case even if he were fresh from his first house-appointment. This practice proved valuable in keeping the sanatorium staff abreast of current medical thought. Although a man of strong personality, he neither claimed nor assumed the rôle of superintendent, and in summing up a discussion on the treatment of a difficult case he would usually agree with his juniors' views while adding valuable comments derived from his long experience. To the end of his life he remained youthful in mind, and his habit of talking on the level with people a generation or more his junior made him a number of happy and lasting friendships. One of these younger colleagues recalls how "an early and unfortunate encounter with the local sanitary inspector, on account of pollution of the brook by the sewage from the growing sanatorium, turned his mind to rural hygiene. His advocacy of Vivian Poore's views on the superiority of the well-kept earth-closet assumed almost religious fervour, and he derived considerable satisfaction in giving his patients, however wealthy or well-born they might be, no option but to contribute to the rich humus which helped the sanatorium garden to win prizes for lovely flowers and delicious fruit and vegetables. When the opposition to his beloved system became irresistible Vere Pearson yielded with the graciousness of Queen Elizabeth in similar circumstances, and set himself, with his usual thoroughness, to the study of the latest and most efficient models of Sir John Harington's new-fangled invention."

Pearson had presided over the Society of Superintendents of Tuberculous Institutions and was a former chairman of the Joint Tuberculosis Council. His published works reflect the trend of his interests: the *State Provision of Sanatoriums* appeared in 1913, the *Growth and Distribution of Population* in 1934, *London's Overgrowth* in 1939, while four years ago in *Men, Medicine, and Myself*, he summed up what he had experienced and thought.

S. R. G. writes: "My own friendship with Pearson began with the foundation of *Tubercle*. Shortly after it started he joined the editorial board on the introduction of his friend Lillingston. The other members in those early days after the first world war were Egbert Morland, Rosslyn Earp, Edgar Collis, Noel Bardswell, and Marguerite Kettle. We forgathered in a room up many flights of stairs at the top of John Bale's printing works, and there was little in the world of tuberculosis we did not discuss with great vigour—from the working out of the Astor report to graduated labour and the new village settlements—while we tried to pick up the threads of the pre-war world of international tuberculosis we had known, and corresponded with Brauer, Sauerbruch, Calmette, and the rest. In all this Pearson with his Fabian background was in his element. His interests in life seemed endless, and his views forthright, whether the subject was his management of the sanatorium farm, or engravings, on which he was an expert judge, or water-colours which he painted well, or Henry George and the single tax. He would turn up at my flat for breakfast at some unearthly hour, or we would meet for dinner in the evening, and the discussions went on fast and furious; but they were always good-tempered and kindly. For years he was a keen follower of Labour and chairman of his county Labour group; but I have an idea that he became discouraged by what he thought to be its wrong-headedness in his later years. He was really an individualist at heart—one of that rapidly disappearing Victorian generation who believed firmly and confidently in getting on with the job oneself. Altogether a most likeable man of great character and a staunch friend and ally."

After he retired Pearson went on a visit to the West Indies, for the scenery of these islands appealed to the artist in him. He died in Jamaica on March 18 at the age of 75. His wife, formerly Miss M. E. Earl of Norwich, whom he married in 1916, survives him with a son and a daughter.

HOWARD STEVENSON

M.A., M.B. R.U.I., F.R.C.S.I.

Mr. Howard Stevenson's death on March 16 breaks another link with the early days of the Belfast medical school.

A son of the late Alexander Stevenson, of Lisburn, he was educated at Methodist College, Belfast, and the Queen's College of the old Royal University of Ireland. He took the B.A. in 1897 and the M.B. in 1900, and the fellowship of the Royal College of Surgeons of Ireland in 1904. After working in the old Royal Hospital in Frederick Street he served on the staff of the Ulster Hospital for Children and Women, and later he became senior surgeon to the Royal Victoria Hospital. In 1938 he was elected M.P. for Queen's University at Stormont, and he was chairman of the Select Committee on Health Services in 1943 and 1944. He served a term as president of the Ulster Medical Society. During the war he returned from retirement to help the Royal Victoria Hospital.

W. S. B. writes: "Stevenson had a great experience of all abdominal surgery, where his sureness of touch and economy of manœuvre gave him a phenomenal operating speed without any suggestion of haste. He will long be gratefully remembered, by all who worked with him, for his unfailing courtesy and consideration to staff and patients alike."

FREDERICK WILLIAM TWORT

M.R.C.S., F.R.S.

Prof. F. W. Twort, who died on March 20 at the age of 72, was superintendent of the Brown Institution of the University of London from 1909 until its destruction by bombing in 1944. An outstanding representative of the independent research-worker, he had made valuable contributions to bacteriology, but he felt himself increasingly uneasy in the closer relationship of research and the State.

He was born at Camberley in 1877, the son of Dr. H. W. Twort, and he qualified from St. Thomas's Hospital in 1900. The following year he was appointed assistant superintendent of the clinical laboratory at St. Thomas's, and in 1902 assistant bacteriologist to the London Hospital, a post which he held till he took charge of the Brown Institution in 1909. He served in the 1914–18 war with the Royal Army Medical Corps in charge of the base laboratory at Salonika and as bacteriologist to the Northern Ireland command.

His earliest work at the Brown Institution was on the cultivation of the lepra bacillus. It extended to the causative organism of Johne's disease of cattle, and tween 1910 and 1913, with G. L. Y. Ingram, he ltivated the bacillus, reproduced the disease from ltures, and made the first attempts to prepare a ecific diagnostic agent analogous to tuberculin. Their servations were summarised in their *Johne's Disease* ondon 1913), and Twort afterwards maintained that he "essential substance" which they recognised was itamin K. In 1913 he began to study the conditions overning the growth of infective agents, and in 1915 e described in our columns some experiments with taphylococci which are now generally accepted as the rst demonstration of bacteriophage action. Unfortun-tely their significance was not recognised, and Twort ater said that lack of support and funds had prevented him from continuing them. Meanwhile, d'Herelle, who had independently made similar observations with dysentery bacilli, carried the investigation further, and his name is now associated eponymously with Twort's in the Twort-d'Herelle phenomenon. Subsequently the University of London supplied Twort with essential equipment for his scheme of research for the cultivation of viruses, and it was a source of distress to him in the last years of his life that he had no opportunity to resume his virus work with such of this equipment as had been salvaged from the institution when it was bombed. He regarded his own experiences as an illustration of the risk to science which may arise from control of research through State grants: but they also illustrated the not uncommon combination of unusual ability with a combative personality.

Dr. Twort's notable contributions were recognised by his election as F.R.S. in 1929 and by his receiving the title of professor from London University. He is survived by his widow, one son, and three daughters.

Prof. JOHN RYLE

Dr. Percy Stocks writes: "Advancing age brings nothing so devastating as the falling by the wayside of tried and valued friends, and for myself the crossing of the threshold of the seventh decade has been accompanied by a double loss of this kind. On arriving home from America a few months ago I was shocked to learn that I should not again see Major Greenwood; and now this experience has been repeated by reading on my return from Paris of the death of John Ryle.

"My first meeting with Ryle was at a Medical Research Council Committee on Hospital Morbidity Statistics in 1942, a remarkable group of clinicians, pathologists, and medical statisticians who came very near to understanding one another's aims and points of view, and who produced, after many meetings, the well-known Provisional Classification of Diseases and Injuries, preparing the way for the International Statistical Classification (1948). In those meetings, and to an increasing extent on other working parties which had to deal later with the beginnings of hospital and other kinds of morbidity statistics, Ryle impressed me by his understanding, not too common in a professor of medicine, of what the medical statisticians were driving at. My associations with him after his appointment at Oxford became closer, and one of the pleasures of going to the new Institute of Social Medicine was the warmth of welcome which always met me when I entered his room. He was not demonstrative, but quiet friendliness radiated from him.

"His small book on *Changing Disciplines*, which embodies in a few lectures the ideas which were taking shape in his mind during those all-too-brief years, is a classic: and at several places in the U.S.A. where Ryle had lectured on his last visit, I found he was held in very high esteem, despite a good deal of theoretical opposition to the idea of social medicine as an entity. They had met the man, and it made a difference.

"Ryle was well aware that a social medicine department must depend for much of its food-supply on the General Register Office, and he always appreciated the work done by the official medical statisticians, and was ever ready to help where he could. The General Register Office is not unmindful of what it owes to such men as Greenwood and Ryle, so different and yet so much alike, and these few sentences are a poor attempt to express this gratitude at the same time as my own feelings of personal loss."

Notes and News

HOT WATER IN THE HOME

In practice hygiene often boils down to hot water, and health education is most effective where there is an adequate supply at those strategic points of a household—the kitchen sink, the bath, and the hand-basin. A survey[1] of the hot-water supplies in 6000 representative households, undertaken for the Ministry of Works in March, 1947, suggests that the housewife still has a good deal to contend with. In 44% of the households there was no piped hot-water supply, and only 36% had a piped supply to sink, bath, and basin. Only 54% of the families had access to a bathroom—this proportion varied from 46% in Scotland to 60% in England —and only 43% had a bathroom of their own. Some 12% (35% in Scotland) did not even claim the doubtful luxury of a portable bath, which was available to 31%. There were hand-basins in only 75% of the bathrooms.

Turning to the question of how the water was heated, the survey found that 15% of the households had no means of heating water and 43% had only a copper. This meant that in 43% housewives had to heat a good deal, if not all, of the water, for such jobs as washing up, in kettles and pans. Between them the hydraulically backward areas of Scotland and London accounted for almost half of these households. Apart from the not very convenient copper, the commonest method of heating water was by a fire with a boiler behind it. This method was used in about a third of the households. As was to be expected, independent boilers and gas and electric appliances were commoner in the higher than the lower income groups, and 6% of the households had a gas or electric appliance as well as a solid fuel appliance.

University of Cambridge

On March 18 the following degrees were conferred:

M.D.—A. G. Freeman, D. N. Lawson, B. E. Miles.

University of London

Sir Ernest Graham-Little is not seeking re-election to the senate, to which he has been re-elected 10 times in succession. Sir Alexander Fleming F.R.S., has been nominated for the vacancy.

University of Dublin

At a recent examination the following were awarded the diploma in gynæcology and obstetrics:

Ahmed Abdel-Fattah Atallah, D. C. G. Bracken, C. A. Cussen, P. B. Guastalla, Shamim Aon Jafarey, J. H. Kühn, Henry Messawer, Max Miller, Nirmal Kumar Mitra, Nina C. Muir, Sunil Kumar Nag, Hyman Neifeld, D. P. J. O'Shea, Peter Pau, Jeffrey Walsh, F. E. Welch.

Dalhousie University

Dr. N. G. B. McLetchie, director of pathological laboratories at Regina, Saskatchewan, has been appointed to the chair of pathology at Dalhousie University, Halifax, Nova Scotia, in succession to Prof. R. P. Smith. Dr. McLetchie is a graduate of the University of Glasgow.

Royal College of Physicians

A course of lectures in general medicine will be given at the college, Pall Mall East, London, S.W.1, from May 1 to June 19. Further particulars will be found in our advertisement columns.

Association of Surgeons of Great Britain and Ireland

The association has decided to award annually, in place of the Moynihan fellowship, a Moynihan prize (£100), and a medal for an essay. For 1951, the subject chosen is Pathology, Prevention, and Treatment of Thrombophlebitis (including Phlebothrombosis); and for 1952, Pathology of the Formation of Calculi. Further particulars will be found in our advertisement columns.

Welsh National School of Medicine

Dr. A. G. Watkins, has been appointed to the newly established professorship of child health. He has been lecturer in pædiatrics at the school since 1932 and he is pædiatrician to the Cardiff Royal Infirmary, the Llandough Hospital, and the Tuberculosis Service in South Wales. He is also adviser in pædiatrics to the Welsh Regional hospital board.

Brussels Treaty Organisation

The fifth session of the public-health committee was held at the Hague on March 9–11. The next session will be in Edinburgh on Sept. 7–9.

British Health Resorts Association

A meeting of this association will be held on Friday, March 31, at 4.30 P.M. at 11, Chandos Street, London, W.1. Dr. A. P. Cawadias, the acting honorary secretary, may be addressed at 6A, Bourdon Street, W.1.

More Spectacles

Before the start of the National Health Service, spectacle manufacturers were supplying spectacles at the rate of about 4,250,000 pairs a year. In December, 1948, the rate of demand reached 12 million a year, but it fell substantially and steadily during 1949, and the present rate is about 5 million a year. Production could not at once keep pace with this sudden acceleration of demand, but the rate has been increased to 7,500,000 pairs a year. It passed current demand early last autumn, and it has steadily risen since, while demand has fallen. About 500,000 have been wiped off the waiting-list since last September, and arrears are now being reduced at the rate of 250,000 a month. In a parliamentary answer on March 23 the Minister said the greater part of the arrears should be overtaken before the end of the year.

Anti-histamine Drugs in the Common Cold

In view of the conflicting reports on the value of anti-histamine drugs in the treatment of the common cold, the Medical Research Council have agreed to arrange an investigation. Trials are being carried out in factories, Civil Service establishments, and other institutions where large numbers of subjects can be studied. Volunteers are requested to report when they have a cold; they are then given tablets to take *and the progress of the cold is assessed during the next week.* Some of the volunteers are given tablets containing the anti-histamine drug under trial; others get tablets containing another compound. In order to obtain results which are *scientifically sound, neither the volunteer nor the doctor* conducting the test knows which type of treatment is being given. The results of the tests will not be known for several months.

Administration of the Hospital Service

The National Federation of Hospital Officers has set up a working party "to consider the administrative structure of the new hospital service and to make recommendations." Brigadier G. Hardy-Roberts (Middlesex Hospital) has accepted the chairmanship, and the following have agreed to serve with him: Captain H. Brierley (London Hospital), S. Clayton Fryers (Royal Infirmary, Leeds), P. H. Constable (St. George's Hospital), P. Essex-Lopresti, F.R.C.S. (Accident Hospital, Birmingham), G. W. Beckwith (Darlington H.M.C.), R. A. Mickelwright (Ealing H.M.C.), J. Rowlandson (chairman, Standing Committee of Finance Officers), L. T. Feldon (Darenth & Stone H.M.C.), and C. C. Carus-Wilson (St. Bartholomew's Hospital). The hon. secretary will be Miss J. Crawford, of the Middlesex Hospital.

Travelling Fellowships in Medicine and Tuberculosis

The Medical Research Council invite applications for the following travelling fellowships for 1950–51:

Rockefeller Medical Fellowships.—These fellowships are intended for graduates resident in this country who have had some training in research work in clinical medicine or surgery, or in some other branch of medical science, and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad, before taking up positions for higher teaching or research in the United Kingdom. The stipend of fellowships tenable in the United States will ordinarily be at the rate of $2600 per annum for a single fellow, and of $3600 per annum for a married fellow. Travelling expenses and some [illegible] paid in addition.

Dorothy Temple C [illegible] *in Tuberculosis.*—The object of these fello [illegible] opportunities for study or research to suit [illegible] subjects of either sex "intending to devo [illegible] ancement by teaching or research of curat [illegible] ment of tuberculosis in all or any of its forn [illegible], as a rule, be awarded to candidates who v [illegible] or inquiries elsewhere than in the United [illegible] inarily be awarded for one academic year. [illegible] rily be at the rate of *£650 per annum fo* [illegible] £900 per annum for a married fellow, sub [illegible] stment in the case of fellowships tenable at centres outside the sterling area, with an allowance for travelling and incidental expenses.

Applications should reach the secretary of the council, 38, Old Queen Street, London, S.W.1, not later than June 1, 1950.

Diary of the Week

APRIL 2 TO 8

Monday, 3rd

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Dr. T. L. Hardy, Mr. Michael Smyth: Ulcerative Colitis.

Wednesday, 5th

NATIONAL HOSPITAL, Queen Square, W.C.1
5 P.M. (Institute of Neurology.) Prof. J. Morelle (Louvain): Neurofibromatosis of the Central Nervous System.

Appointments

ASTLEY, C. E., M.D. Leeds, M.R.C.P.: cons. physician, Teesside group of hospitals.

CHARRETT, M. A., M.R.C.S., D.P.H.: M.O.H., borough of Weston-super-Mare and area M.O. to Somerset county council.

CHIN, E. F., M.B. Sydney, F.R.C.S.: part-time asst. thoracic surgeon (cons.) to Godalming, Milford, and Liphook (Surrey) group of sanatoria.

DEWAR, D. C., M.D. Glasg., D.P.M.: cons. psychiatrist, Brookwood Hospital, Knaphill, Woking.

FOULKES, S. H., M.D. Frankfurt, L.R.C.P.E.: part-time physician (cons.), Bethlem Royal Hospital and Maudsley Hospital, London.

FREW, J. M., M.B. Glasg., D.P.M.: cons. psychiatrist, Brookwood Hospital, Knaphill, Woking.

HARLEY, H. R. S., M.S. Lond., F.R.C.S.: part-time asst. thoracic surgeon (cons.), Godalming, Milford, and Liphook (Surrey) group of sanatoria.

MACDONALD, RODERICK, M.B. Edin., D.P.M.: physician-superintendent and cons. psychiatrist, Banstead Hospital, Surrey.

ROSS, H. L., M.B. Durh., M.R. Lpool, D.M.R.D.: cons. radiologist, *Coventry group of hospitals, mainly at* Hospital of St. Cross, Rugby.

SLOAN, W. R., M.D. Belf., F.R.C.S.E., M.R.C.O.G.: cons. in obstetrics and gynæcology, Samaritan Hospital, Belfast.

TAYLOR, W. K., B.SC. Lond., M.R.C.P., D.C.P., F.R.I.C.: cons. pathologist, Godalming, Milford, and Liphook (Surrey) group of sanatoria.

Births, Marriages, and Deaths

BIRTHS

BECTOR.—On March 14, in London, the wife of Dr. N. P. Bector—a daughter.

BENNETT.—On March 19, at Liverpool, the wife of Dr. N. O. Bennett—a son.

BRAND.—On March 21, the wife of Dr. Terence A. Brand—a daughter.

BUCHAN.—On March 21, in London, the wife of Dr. Ian Buchan—a daughter.

GENT.—On March 20, in Malta, the wife of Surgeon Lieutenant N. S. C. Gent, of Frampton, Dorset—a son.

HIRD.—On March 22, at Carshalton, to Dr. Mary Sharpe, wife of Dr. G. F. Hird—a daughter.

KEATING.—On March 23, at Birkenhead, the wife of Dr. R. J Keating—a daughter.

LUNDIE.—On March 17, at Wantage, the wife of Major A. R. T. Lundie, M.C., R.A.M.C.—a daughter.

PHILLIPS.—On March 23, in London, the wife of Dr. E. H. P. Phillips—a daughter.

WOODALL.—On March 22, in London, the wife of Dr. John Woodall—a daughter.

MARRIAGES

WATERS—KOHLER.—On March 21, in London, Harry Waters, M.B., to Irene Kohler.

DEATHS

BROWNE.—On March 20, at *Great Missenden*, Robley Browne, O.B.E., L.R.C.P., surgeon captain, R.N. retd, aged 86.

DAVIES.—On March 25, at Winchester, Henrietta Frances Davies, M.B. Lond., aged 70.

EVANS.—On March 20, at Forest Green, Surrey, Arthur Henry Evans, O.B.E., M.D., M.S. Lond., F.R.C.S.

MILROY.—On March 20, at North Berwick, Thomas Hugh Milroy, M.D., LL.D. Edin., D.SC. N.U.I. and Belf., F.R.S.E.

PEARSON.—On March 18, in Jamaica, Sidney Vere Pearson, M.D. Camb., M.R.C.P., of Mundesley, Norfolk, aged 75.

PROCTOR.—On March 23, at Hexham, Northumberland, Alfred Henry Proctor, D.S.O., M.D., M.S. Durh., F.R.C.S.E., colonel, I.M.S. retd.

SUFFERN.—On March 21, at Hill Head, Fareham, Hants, Alexander Canning Suffern, O.B.E., M.D. R.U.I., lieut-colonel, R.A.M.C. retd, aged 92.

TWORT.—On March 20, at Camberley, Frederick William Twort, M.R.C.S., F.R.S., aged 72.

Dr. Stephen Taylor has been appointed a member of the Beveridge Committee to inquire into the organisation of British broadcasting.

Mr. Rainsford Mowlem and Dr. H. W. Davies left this country on March 21 for a visit, under the auspices of the British Council, to Yugoslavia. There they are lecturing and demonstrating the techniques of plastic surgery and *anæsthesia.*

SYMPATHECTOMY IN HYPERTENSION

ROBERT PLATT
M.Sc. Manc., M.D. Sheff., F.R.C.P.
PROFESSOR OF MEDICINE, UNIVERSITY OF MANCHESTER

S. W. STANBURY
M.B. Manc., M.R.C.P.
BEIT MEMORIAL RESEARCH FELLOW AND PART-TIME RESEARCH ASSISTANT, DEPARTMENT OF MEDICINE, UNIVERSITY OF MANCHESTER

A PRELIMINARY and tentative account of our early experience with sympathectomy in the treatment of hypertension has already been published (Platt 1948). The present paper is concerned with the results of operation in 80 patients, some of whom have been followed for two to three years. The series is small and some of the cases have been followed for a relatively short time; the results in many of them, however, are so clearly unsatisfactory that a more prolonged follow-up is not necessary to confirm the frequency with which the procedure fails to relieve high blood-pressure.

The fact that our results are on the whole considerably worse than in many published series we do not ascribe to inadequate medical or surgical treatment. On the contrary, we believe that many, if not most, of the good results reported by other authors are due to three factors: (1) insufficient control, with failure to observe the blood-pressure for a long enough time before operation is performed; (2) failure to appreciate the great variability of blood-pressure in benign hypertension; and (3) ignorance of the natural history of benign essential hypertension, with lack of appreciation of its relatively good prognosis in most of the milder cases.

We believe that the majority of cases of essential hypertension can, from the point of view of sympathectomy, be divided into two classes—namely, those which are too mild to warrant the use of this serious operation, and those which are too severe, too old, or too arteriosclerotic to benefit from it. Despite this general condemnation we have to admit that there is a small middle group in which sympathectomy has, even judged by the strictest of standards, produced real, apparently lasting, and significant benefit. We shall, so far as possible, attempt a clinical definition of this group. For the rest, the results of operation will speak for themselves.

THE PROGNOSIS OF HYPERTENSIVE DISEASE

The commonest cause of death from hypertensive disease is heart-failure, and this is most liable to occur between the ages of 55 and 65. Since this is not an age-group for which sympathectomy is seriously contemplated by any of its advocates, this group need not concern us further. All physicians with much experience of hypertension realise that, when discovered accidentally in a comparatively young person, it is often compatible with many years of life, and commonly gives rise to no symptoms unless an anxiety state is superimposed by the discovery of the disorder and too frequent estimation of the blood-pressure. It is well known that the prognosis throughout is better in women than in men. Bechgaard (1946) and Burgess (1948) have made important observations on the natural history of untreated hypertension, and their mortality figures must be taken into account in assessing survival after sympathectomy. It is apparent from their studies that moderate hypertension may be associated with no significant increase in mortality; and that patients with diastolic pressures of over 120 mm. Hg on first estimation may survive for more than fifteen years.

Hypertension is a clinical phenomenon and not a disease. The height of the blood-pressure is not necessarily an accurate index of the severity of the basic disease processes, nor is it an infallible guide to prognosis. Clinical experience teaches that the more serious case is usually associated with the higher blood-pressure; but sometimes cerebral thrombosis or cardiac failure will occur unexpectedly in patients with a diastolic blood-pressure of no more than 120 mm. Hg. The individual response to the establishment of permanent hypertension, and thus the individual prognosis, cannot therefore be forecast. It is, however, a firm clinical fact that when the diastolic blood-pressure becomes permanently raised to very high levels (130–140 mm. Hg or more) serious complications such as retinopathy, heart-failure, and renal failure are probable and the hypertension tends to enter its "malignant phase." This may happen irrespective of the cause of the hypertension, and is particularly likely when inordinately high pressures develop in young people. Despite the dissent of Goldblatt (1947), clinical experience suggests that it is the severe hypertension itself which brings about the "malignant deterioration"; and we believe that the experimental work of Wilson and Byrom (1941) and Byrom and Dodson (1948) offers strong support for this concept. Accepting this premise, sympathectomy producing significant and permanent reduction of blood-pressure would be of prophylactic value in such cases. The operation would not cure the disease, and there is little to suggest that it in any way alters or reverses the basic disease processes of which hypertension is but one effect.

OTHER REPORTS

We do not intend to review the extensive literature on sympathectomy in hypertension. Too often, reports fail to give adequate clinical information about the patients submitted to operation, and the reader has no opportunity of judging to what extent the inclusion of mild cases predetermines favourable operation statistics. Even the careful and critical account of Hammarström (1947), which records details of every case, includes many with diastolic pressures of less than 100 mm. Hg—cases which in our view would be likely to survive without operation and without disability for very many years. The series of so-called malignant hypertension reported by Peet and Isberg (1948) includes several cases in which the preoperative diastolic pressure was less than 120 mm. Hg—a level at which, in our experience, the changes of true malignant hypertension are not found. It will thus be seen that our series is difficult or impossible to compare with that of any so far published; our comparatively bad results are to be judged only after acceptance of the premise that mild cases of hypertension do not justify this serious operation, and that there is no evidence that their lives are prolonged by it.

SELECTION OF CASES

Cases selected for sympathectomy had usually presented with diastolic pressures of 130 mm. Hg or more when the patient was ambulant, and which tended to be 120 mm. or more with the patient at rest in bed. As bed rest was prolonged, the diastolic pressure sometimes fell below 120 mm. (see figs. 3, 4, 5, and 7 and table II). All were free from serious cardiac insufficiency and had renal function that was "reasonably good." (In this context "reasonably good" implies a urea-clearance of not less than 50–60% of the average normal, and, with a few exceptions, the ability to produce urine with a specific gravity of at least 1·016.)

The age and sex distribution is shown in fig. 1. Definite papillœdema was present in 24 cases, which are thus classified as "malignant type of hypertension"; in 51 the diagnosis was believed to be "essential" hypertension; in 16 there appeared to be a primary renal cause; and in 12 no diagnosis could be made. There was 1 case of phæochromocytoma.

METHOD OF ASSESSMENT

All cases had routine electrocardiograms and six-foot skiagrams of the chest before operation. No systematic study was made of the changes induced in these by operation; this aspect has been surveyed by Canabel et al. (1945). Unpublished observations by one of us (S. W. S.) have shown that renal function in hypertensive disease, whether measured by urea-clearance, concentrating capacity (specific gravity), or even inulin and *p*-aminohippurate clearances, shows very wide spontaneous variability. It was therefore difficult to assess the effect of the operation on renal function. The retinal appearances before operation have been carefully recorded, with particular attention to the presence of papillœdema, retinal hæmorrhages, and exudates. We feel convinced that not all observers recording the effects of sympathectomy in hypertension make the distinction between true papillœdema and œdema of the peripapillary retina. Adequate assessment of serial changes in retinal vessels is practically impossible without the help of photography and the detailed recording of every stretch of blood-vessel. We are unimpressed by reports which grade retinal appearances by a series of "pluses" and attempt a pseudostatistical assessment of the results of operation in terms of these highly subjective gradings.

The only available objective measure of the effects of operation is the blood-pressure, and in the first instance we shall define the success or failure of operation purely in terms of blood-pressure. Symptomatic relief will be discussed later. The difficulties involved in the assessment of blood-pressure changes have been emphasised by Evelyn et al. (1949), whose methods represent the best approach to the problem. In some of our cases we have records, as had Evelyn and his colleagues, of blood-pressures for some years before operation, taken when the patients were up and about as outpatients. In most we have one or two outpatient readings, the pressure on admission to hospital, and measurements throughout a period of some weeks at rest in a medical ward; during this last period blood-pressure was measured daily and the patient often did not know that surgery was contemplated. After operation the patient was seen as an outpatient at a special clinic where recumbent and standing blood-pressures were measured after about 15 minutes' rest. There are thus available for comparison with the postoperative readings, preoperative values representing probable maximal psychic pressor effects (initial attendance at the outpatient department and the first day in hospital) and readings representing the therapeutic effect of bed rest. The way in which we assess such a comparison will be described when we discuss our "failures" and "successes."

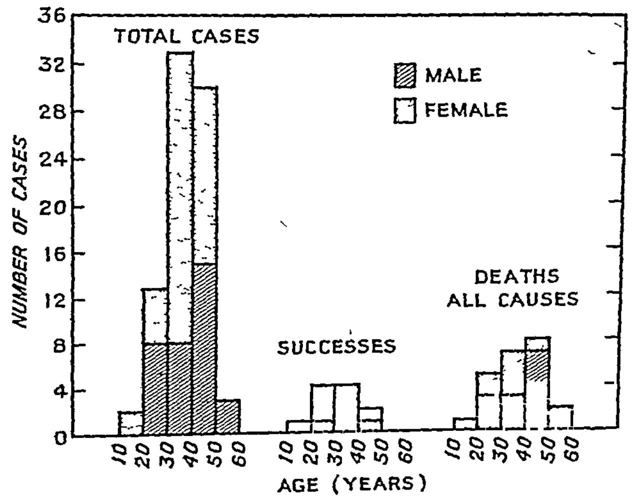

Fig. 1—Distribution by age and sex of total cases, "successes," and deaths from all causes.

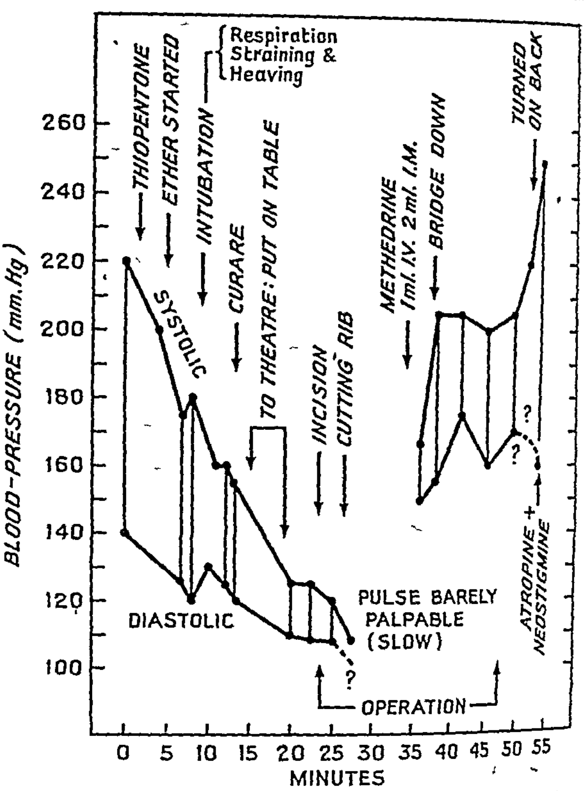

Fig. 2—The effects of anæsthesia, positioning, operation, and methedrine on the blood-pressure in a case of malignant hypertension (man, aged 49 years).

Operations and Results

The cases fall into six groups according to the operation performed:

1. The *Smithwick dorsolumbar operation* with ganglionectomy from D9 to L3 (19 cases).
2. The *Adson subdiaphragmatic splanchnic resection* with removal of ganglia L1, 2, and 3 (3 cases).
3. The *Boyd operation* (30 cases). This operation, which produces a sympathectomy extending from D4 to L5, involves a transthoracic approach, and it has been found desirable to carry it out in three or four stages.
4. "*Adson +*."—For various reasons the physician members of the team have sometimes thought it undesirable to proceed with the final transthoracic operation. This has given rise to a fourth group (14 cases), which we shall call Adson +, in which bilateral subdiaphragmatic splanchnic section and lumbar ganglionectomy has been performed, together with a thoracic sympathectomy from D4 to D12, on one side only.
5. "*Total*" *sympathectomy* (1 case).
6. *Uncompleted operations.*—In addition, 12 patients have died after the first stage of a sympathectomy (not necessarily as a result of the operation) and thus cannot be included in any of the above categories.

A few of the cases were operated on by Prof. Geoffrey Jefferson and by Mr. H. T. Simmons, but by far the greater part of the surgical work has been done by Prof. A. M. Boyd, who has coöperated throughout in this investigation. He will publish separately an account of the surgical procedures.

Of the 80 patients submitted to operation, only 11 (14%) subsequently had a significant and maintained reduction in the recumbent blood-pressure (see fig. 1) 11 patients have died after discharge from hospital and 1 defaulted, refusing further operation after unilateral thoracic sympathectomy. Table I presents the results obtained by the different techniques.

THE DEATHS

Of the 80 patients reviewed 23 are dead—i.e., 44·1% of all the males and 17·4% of all the females, submitted to operation. These figures are for the most part a measure of the severity of the cases selected by the physicians—a selection which precludes "good" operation statistics.

In 4 female cases, death must be regarded as accidental; the causes were subarachnoid hæmorrhage from congenital cerebral aneurysm, accident involving anæsthetic apparatus, adrenaline intoxication from extra-adrenal phæochromocytoma (not discovered at operation), and sudden death following intravenous administration of 1% procaine. Omitting these, the female death-rate is reduced to 8·7%. The remaining 4 female deaths are accounted for as follows:

Age	*Diagnosis*	*Operation*	*Mode and time of death*
17	Hypoplastic kidney; pyelonephritis	D4–12, one side	Congestive cardiac failure, 16 months after operation
37	Essential hypertension	Boyd complete	Acute pulmonary œdema, after second thoracic operation
44	Malignant essential hypertension	Subdiaphragmatic, one side	Postoperative collapse
44	Malignant essential hypertension	Smithwick complete	Uræmia, about one year after operation

One male died after intravenous procaine. It could fairly be said that two others were submitted to operation in desperation: one, a man aged 25 years, with type-2 nephritis and hypertension in the malignant phase, died of uræmia eight months after a unilateral Smithwick operation; the other, a physician, aged 35, with recurrent heart-failure, died a few days after completion of the Boyd operation. The remaining 12 male deaths are accounted for as follows:

TABLE I—RESULTS OF VARIOUS SURGICAL PROCEDURES IN 80 CASES OF HYPERTENSION

Type of operation	No. of operations completed	No. successful	Deaths since completion of operation
Boyd	30	4	4
Smithwick	19	4	4
"Adson +" ..	14	Nil	2
Adson	3	2	1
"Total"	1	1	Nil
Total ..	67	11	11

None of the "successes" is included in "died since completion." 12 patients died and 1 defaulted, before completion of the operation.

Of 6 cases of malignant essential hypertension 1 (aged 43) died of cardiac failure after a unilateral Smithwick operation; 3 (aged 48, 50, and 53) died at home of cardiac failure before completion of their operations; and 2 (aged 38 and 45) died of uræmia approximately two years and one year after completion of the Smithwick operation.

Of 3 cases of severe essential hypertension with well-marked arteriosclerosis, 1 (aged 42) passed into coma following the unilateral Smithwick operation, and autopsy revealed cerebral œdema; 1 (aged 52) died two days after completion of the Boyd operation from cardiac failure; and the third (aged 45) died at home, probably from coronary occlusion, three years after completion of the Smithwick operation.

The remaining 3 were cases of chronic type-1 nephritis or pyelonephritis with hypertension of malignant type. Of these, 1 (aged 28) completed the Adson operation and died of heart-failure a few months later; 2 completed the Boyd operation, 1 dying of uræmia 6 months later (aged 24), and the other of uncertain cause 3 months later (aged 31).

Perhaps the most interesting point that emerges from consideration of these mortality figures relates to the presence of papillœdema. Of the 24 patients with papillœdema (14 males and 10 females) submitted to operation, 8 (57%) of the males and 3 (30%) of the females have died, either at or after operation. Of the males with papillœdema, 4 of the 7 below 40 years of age, and 2 of the 4 below 30 years of age, have died.

We were alarmed by the occurrence, in some of our earlier cases of severe benign or malignant hypertension, of fatal postoperative collapse and acute cardiac failure following even short and relatively mild operations; so an attempt was made to follow blood-pressure changes throughout the operation. Fig. 2 is constructed from data obtained by one of us (S. W. S.) before and during a transthoracic operation on a male, aged 49, with malignant hypertension. Preoperative thiopentone and tetraethylammonium depressor tests had reduced the diastolic pressure by no more than 10–15 mm. Hg from the usual level of 140 mm. Hg. At operation the blood-pressure fell to 125/105 before surgery actually commenced, and

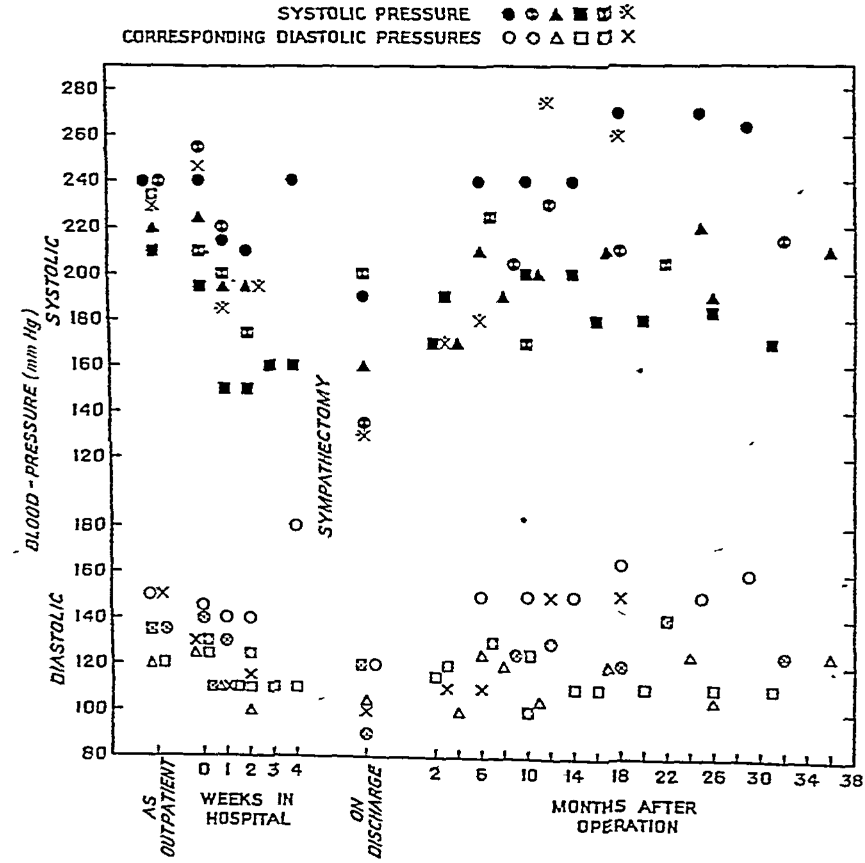

Fig. 3—Scatter diagram of blood-pressure readings obtained in six patients submitted to the Smithwick operation. Comparison is made of pressures before operation, both as ambulant outpatient and at rest in bed; on completion of operation; and ambulatory after operation.

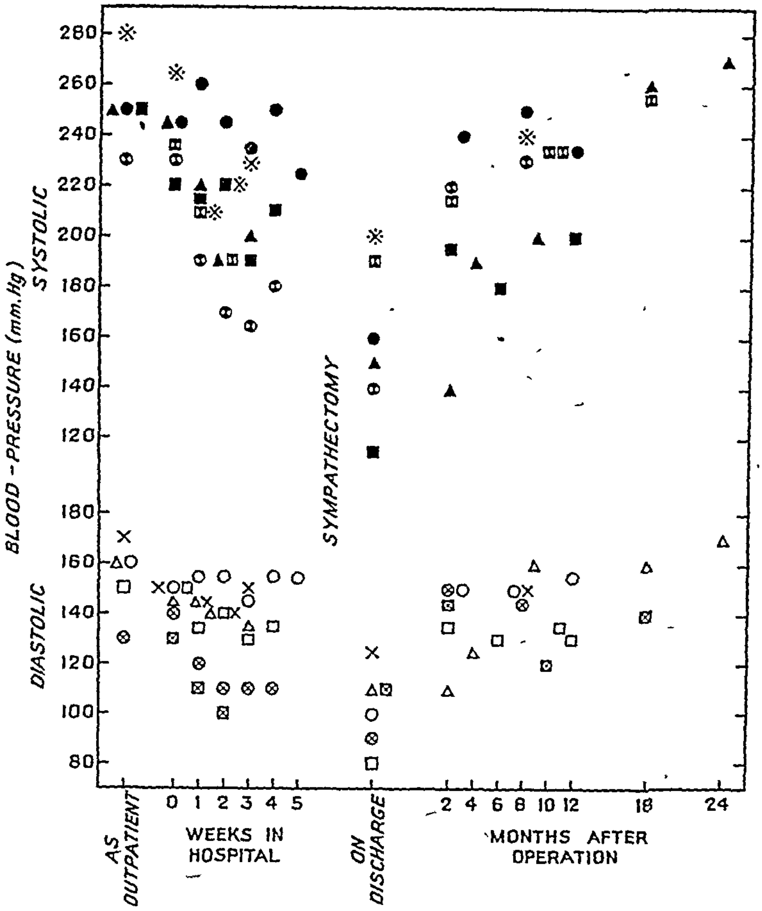

Fig. 4—Scatter diagram of blood-pressure readings obtained in six patients submitted to the Boyd operation. Key as for fig. 3.

during the operation no readings could be obtained by palpation or auscultation until 'Methedrine' was given. Such a profound hypotension could produce severe cardiac or cerebral ischæmia and might easily lead to arterial thromboses in diseased vessels. It seems likely that the hypotension is produced by the combination of loss of venomotor control due to anæsthesia and, perhaps, to interference with venous return through moving and positioning the patient. Methedrine appears to control this hypotensive state, and an attempt is now made to maintain the blood-pressure at its initial level with the aid of this drug. There have been no further inexplicable early postoperative deaths since this procedure was instituted.

THE FAILURES

Considerable difficulty is met in assessing the significance of minor differences between preoperative and postoperative blood-pressures. If all recumbent diastolic pressures measured in the ambulant outpatient after operation remain equal to, or higher than, the highest recorded before operation, the treatment has undoubtedly been ineffective; and this happened in a proportion of the cases classified as "failures."

In other cases the diastolic pressure after operation has appeared to be reduced by 20 mm. Hg or less, compared with the high levels when the patient first attended the outpatient department. We cannot maintain that this represents a "successful" result of operation, for several reasons: (1) the postoperative levels were almost always well above the levels achieved with bed rest before operation; (2) changes of 20 mm. Hg are well within the range of spontaneous variation in even the most "fixed" states of hypertension (Hammarström 1947); (3) isolated readings about as high as the preoperative outpatient readings have been seen in nearly all these cases; and (4) we do [illegible] feel satisfied that in a patient with diastolic pressures of 140–150 mm. Hg a reduction [illegible] less than 20 mm. Hg represents a worth-while return for an extensive surgical procedure. When operation has produced significant changes in blood-pressure this is obvious, as will be seen when the 11 "successful" cases are discussed and when figs. 3 and 4 are compared with figs. 5 and 7. In fact, the "failures" and "successes" can be used reciprocally as control groups.

Taking these facts into account, we have to record 54 "failures," 11 of which are included in the "deaths since completion of operation." In figs. 3 and 4 are charted blood-pressure readings obtained from 6 cases submitted to the Smithwick operation and 6 submitted to the Boyd operation; after operation the first group was followed for eighteen months or more, and the second for eight months or more. It is clear that, both individually and collectively, operation has failed to influence the recumbent blood-pressure in these 12 cases. Similar considerations apply to the 42 remaining cases. The figures *also show clearly* the apparently satisfactory, but misleading, reduction in blood-pressure when the patient *is discharged* from the surgical ward.

Of the failures, 15 [illegible] Smithwick operation and 4 of these hav[illegible] and 1 "benign"). developed *uræmia one, two,* and three years after operation, and the 4th ("benign") *died, probably of coronary* occlusion, three years after operation. We have the results of 'Amytal' depressor tests in 7 of these failures (including the 6 cases used in *constructing fig. 3*). These give basal figures of 125/85, 130/100, 140/100, 155/100, 185/135, and 220/130 mm. Hg. It is obvious that these depressor-test results are unrelated to the results of sympathectomy.

It was with these results in mind that the more extensive Boyd operation was undertaken, and little weight was given to the result of depressor tests (thiopentone and tetraethylammonium) in making the decision to operate. Of 30 completed Boyd operations, 26 were failures by *the criteria discussed above*; of these, 4 have died, 2 a day or two after operation, and 2 three and *six months later.*

It is necessary to give a few details of the 14 patients who have had the "*Adson+*" operation. Of these, 2 have died; in 1 pregnancy has interfered with surveillance; and 1 has been completed too recently for

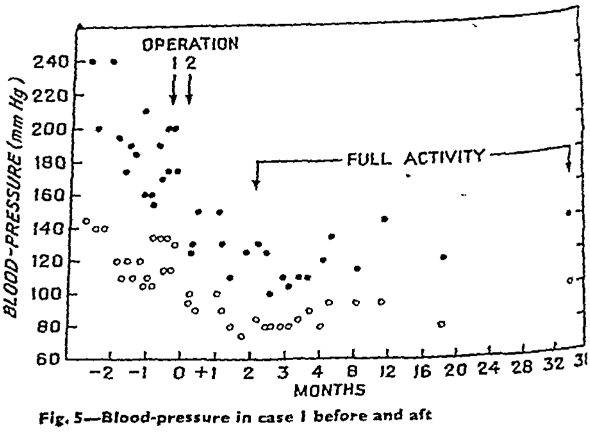

Fig. 5—Blood-pressure in case 1 before and aft

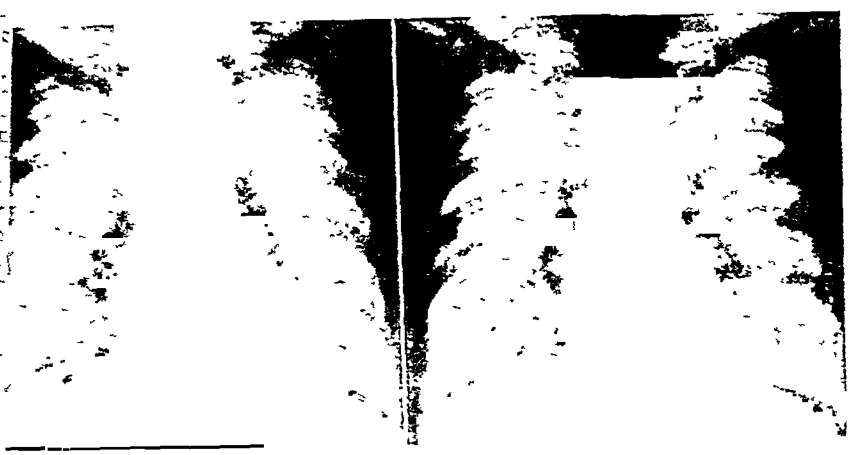

Fig. 6—Radiograph of chest in case 1, before and six months after operation.

adequate assessment. The remaining 10 are failures on the above criteria. Of these 10, 3 have since had a further operation and are converted to Boyd operations but have not yet been assessed as such; in 5 others we shall not recommend completion because of heart-failure and bronchitis (1), development of angina pectoris (1), severe cerebral thrombosis (1), and psychological disturbance in middle-aged females (2).

THE "SUCCESSFUL" CASES

The number of successful cases in which a significant and maintained reduction in blood-pressure has been produced is small and we must therefore devote more detailed attention to these patients. It must be admitted that most of them had been followed preoperatively for too short a time to permit adequate assessment of the rate of progress of the disease, and at least 1 (table II, case 5) would now be regarded as too mild for operation. On the other hand, in view of the serious prognosis associated with sustained high diastolic pressure in youth, one is little inclined to temporise in young patients if there is any hope that therapy will reduce the blood-pressure. Before operation 2 of our female patients had developed mild cerebral thromboses (with recovery of function) at the ages of 27 and 32 years (table II, cases 9 and 10).

All these successful cases have been observed at rest in hospital before operation for several weeks: in all of them, the blood-pressures measured postoperatively in the outpatient department were as low as, or considerably lower than, the lowest pressure recorded at rest in bed. Postoperative outpatient diastolic readings have remained 20–35 mm. lower than the *lowest* pre-operative outpatient reading, and 30–75 mm. below the highest casual outpatient reading. In most cases this state has been maintained for about two years. We would admit that blood-pressure readings obtained at successive visits to a hypertensive clinic may become substantially lower than the initial value, but we have followed a very large number of hypertensive patients in the last three or four years without meeting any case which showed a fall in clinic blood-pressure readings approaching the fall following sympathectomy in these few patients; and we believe that in these cases the attempt to reduce blood-pressure by surgical means has succeeded. Whether or not these desirable results will be maintained, and whether the progress of the underlying disease process has been changed it is still impossible to say.

It is difficult to determine from so small a group of "successful" cases what may be the factors determining a favourable operative result. None had entered into the malignant phase of the disease and all had "normal" renal function, but the response to depressor tests was not uniformly good. The preponderance of females and the general youth of the patients is obvious (table II). Cases 1, 2, 4, 5, 6, 8, 9, 10, and 11 had retinal arterioles which would probably have been passed as normal had the patients been normotensive. Cases 3 and 7 had clear-cut hypertensive vascular changes in the retina, and each presented retinal hæmorrhages; they are 2 of the 3 older patients in the series. It may be that the better results in these younger patients are related to the probable shorter duration of established hypertension and thus to the shorter time during which the hypertension itself could have produced irreversible vascular changes.

There is a possible analogy in the field of experimental hypertension. Flasher and Drury (1949) have shown that when hypertension is produced by unilateral renal interference in the rabbit, the longer the established hypertension is allowed to persist before operation, the fewer the cases that revert to normal blood-pressure after nephrectomy. They believe that long-continued high blood-pressure is a characteristic that tends to be self-perpetuating. In rats, audiogenic stimulation will produce hypertension which is said to subside on withdrawal of the stimulus (Medoff and Bongiovanni 1945). Smirk (1949) has shown that if stimulation is sufficiently prolonged hypertension persists despite removal of the stimulus.

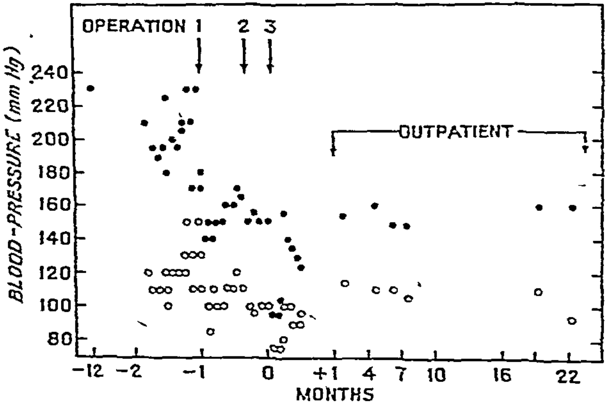

Fig. 7—Blood-pressure in case 3 before and after operation.

Data on the 11 successful cases are summarised in table II; and 3 illustrative case-records follow.

Essential Hypertension in a Young Man

Case 1.—A 27-year-old R.A.F. corporal, who was completely free from symptoms, was found at examination for life assurance to have a blood-pressure of 240/140 mm. Hg. Several times during the next few weeks different doctors recorded similar pressures, and it was found that the pressure fell to 140/100 mm. Hg with 'Sodium amytal' sedation. During four weeks as an inpatient in the Manchester Royal Infirmary the blood-pressure varied from 210 to 155 mm. systolic and the diastolic from 135 to 105 mm. Hg.

A Smithwick dorsolumbar sympathectomy (Mr. Simmons) was then performed in two stages. In fig. 5 are charted all blood-pressure readings obtained before operation and during the subsequent three years with the patient at full duty. He now indulges in weight-lifting and wrestling, and has no symptoms. Postoperatively the outpatient diastolic pressure has remained between 80 and 100 mm. Hg.

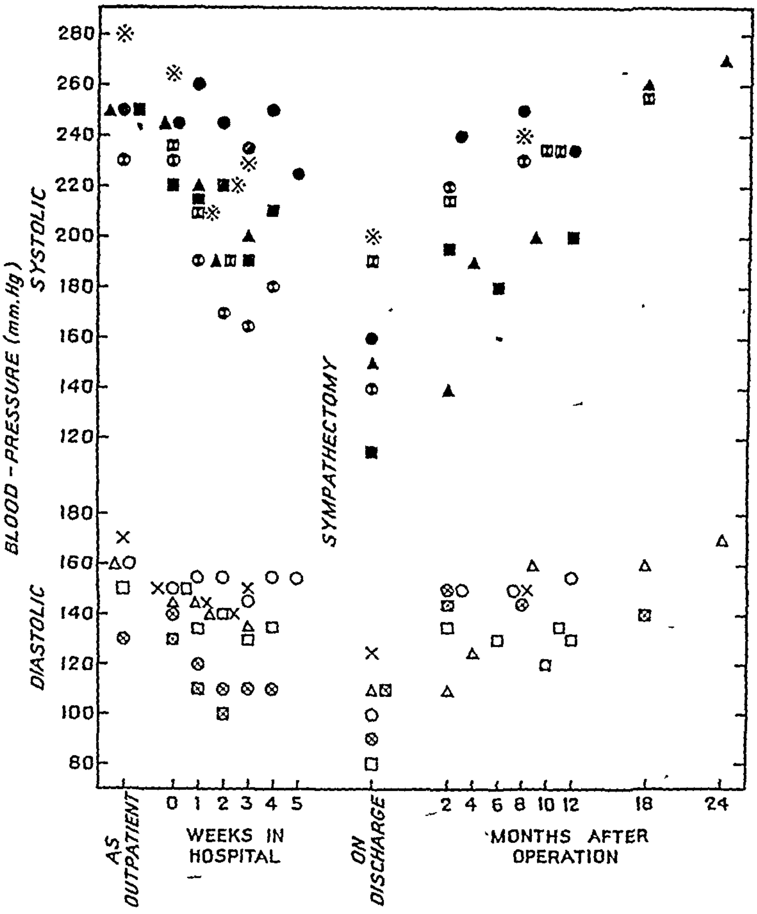

Fig. 4—Scatter diagram of blood-pressure readings obtained in six patients submitted to the Boyd operation. Key as for fig. 3.

during the operation no readings could be obtained by palpation or auscultation until 'Methedrine' was given. Such a profound hypotension could produce severe cardiac or cerebral ischæmia and might easily lead to arterial thromboses in diseased vessels. It seems likely that the hypotension is produced by the combination of loss of venomotor control due to anæsthesia and, perhaps, to interference with venous return through moving and positioning the patient. Methedrine appears to control this hypotensive state, and an attempt is now made to maintain the blood-pressure at its initial level with the aid of this drug. There have been no further inexplicable early postoperative deaths since this procedure was instituted.

THE FAILURES

Considerable difficulty is met in assessing the significance of minor differences between preoperative and postoperative blood-pressures. If all recumbent diastolic pressures measured in the ambulant outpatient after operation remain equal to, or higher than, the highest recorded before operation, the treatment has undoubtedly been ineffective; and this happened in a proportion of the cases classified as "failures."

In other cases the diastolic pressure after operation has appeared to be reduced by 20 mm. Hg or less, compared with the high levels when the patient first attended the outpatient department. We cannot maintain that this represents a "successful" result of operation, for several reasons: (1) the postoperative levels were almost always well above the levels achieved with bed rest before operation; (2) changes of 20 mm. Hg are well within the range of spontaneous variation in even the most "fixed" states of hypertension (Hammarström 1947); (3) isolated readings about as high as the preoperative outpatient readings have been in nearly all these cases; and (4) we do feel satisfied that in a patient with [illegible] pressures of 140–150 mm. Hg a [illegible] less than 20 mm. Hg represents a w[illegible] return for an extensive surgical [illegible]. When operation has produced significant change in blood-pressure this is obvious, as will be [illegible] when the 11 "successful" cases are discussed and when figs. 3 and 4 are compared with figs. 5 and 7. In fact, the "failures" and "successes" can be used reciprocally as control groups.

Taking these facts into account, we have to record 54 "failures," 11 of which are included in the "deaths since completion of operation." In figs. 3 and 4 are charted blood-pressure readings obtained from 6 cases submitted to the Smithwick operation and 6 submitted to the Boyd operation; after operation the first group was followed for eighteen months or more, and the second for eight months or more. It is clear that, both individually and collectively, operation has failed to influence the recumbent blood-pressure in these 12 cases. Similar considerations apply to the 42 remaining cases. The figures also show clearly the apparently satisfactory, but misleading, reduction in blood-pressure when the patient is discharged from the surgical ward.

Of the failures, 15 [illegible] "risk operation" and 4 of these hav[illegible] and 1 "benign"). developed uræmia one, two, and three years after operation, and the 4th ("benign") died, probably of coronary occlusion, three years after operation. We have the results of 'Amytal' depressor tests in 7 of these failures (including the 6 cases used in constructing fig. 3). These give basal figures of 125/85, 130/100, 140/100, 155/100, 185/135, and 220/130 mm. Hg. It is obvious that these depressor-test results are unrelated to the results of sympathectomy.

It was with these results in mind that the more extensive Boyd operation was undertaken, and little weight was given to the result of depressor tests (thiopentone and tetraethylammonium) in making the decision to operate. Of 30 completed Boyd operations, 26 were failures by the criteria discussed above; of these, 4 have died, 2 a day or two after operation, and 2 three and six months later.

It is necessary to give a few details of the 14 patients who have had the "Adson+" operation. Of these, 2 have died; in 1 pregnancy has interfered with surveillance: and 1 has been completed too recently for

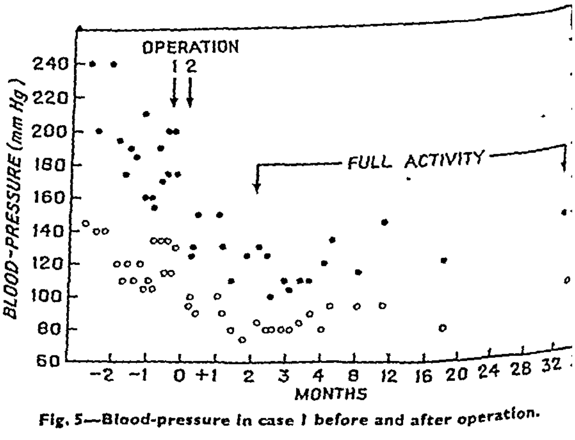

Fig. 5—Blood-pressure in case 1 before and after operation.

ibrosa. The appearances are those of hypertension with evidence of progressive renal damage: chronic pyelonephritis cannot be eliminated by examination of a single segment of kidney."

The patient left hospital fourteen weeks after admission, with a blood-pressure of 130/75 mm. Hg and pulse-rate of 64 per min. (recumbent), postural hypotension of 60/40 mm. Hg, and postural tachycardia of 144 per min. Postural giddiness subsided in two months. Subsequent readings obtained in the outpatient department were as follows:

Months after operation	*Lying* B.P. (mm. Hg)	Pulse-rate per min.	*Standing* B.P. (mm. Hg)	Pulse-rate per min.
5	170/115	96	125/90	112
9	160/105	85	115/80	140
14	145/105	80	145/100	100
19	145/95	88	135/95	128

For some months after operation the patient was subject to more severe asthmatic attacks, and to severe dyspnœa with asthma on exertion. At a year after operation she had few asthmatic attacks, no headaches, and felt well, though she was still easily tired by exertion. The retinal exudates disappeared and have not recurred.

We repeatedly see in young women cases where pyelonephritis is associated with a malignant type of hypertension and with a uræmic termination. We feel convinced that the hypertension itself contributes materially to the development of uræmia, and that in the case recorded above the operative reduction of the blood-pressure from dangerous levels should help to defer indefinitely the development of renal failure. Cases of this type may be the best suited for sympathectomy.

Essential Hypertension

Case 3.—A man, aged 43 years, had suffered from headaches for about a year and had recently developed typical migraine with visual phenomena. Five years ago a systolic pressure of 180 mm. Hg was recorded, and a year ago one of 230 mm. During a month at rest in hospital the systolic blood-pressure varied from 230 to 170 mm. and the diastolic from 150 to 100. Renal function was normal. The heart was slightly enlarged and there were a few small superficial retinal hæmorrhages with fairly well-marked vascular changes. Sympathectomy (D4–L3) was performed by Professor Boyd in three stages, and two weeks after its completion the blood-pressure was 125/90 mm. Hg recumbent and 75/50 standing. When the patient was last seen, two years after the operation, the recumbent pressure was 160/95 falling to 140/95 on standing; he was well and free from symptoms. Blood-pressure readings in this patient are charted in fig. 7.

In this case the result is not so spectacular as in our other "successful" cases; but even here it is significant that a patient who had diastolic pressures of 130–150 mm. at rest in bed now has ambulatory pressures no higher than 110 mm. Hg.

Symptomatic Results

Assessment of the results of operation has so far been confined to its effect on the recumbent blood-pressure. Even when the postoperative blood-pressure remains equal to, or higher than, preoperative levels there may be obvious symptomatic improvement in headaches and retinopathy. On the other hand, whether the operation is a "failure" or "success" from the standpoint of the hypertension, adverse symptoms may be produced, such as postural hypotension and tachycardia, severe exertional tachycardia and fatigability, cold hands or intensification of Raynaud's phenomena, or exacerbation of the asthmatic state. (The effect of the operation on the male sexual function will be reported elsewhere.)

A fair proportion of the most severe cases of hypertension never have headache. Of our patients, 33 who have lived long enough for assessment had significant and often very severe headache before operation: in 29 of these, operation afforded virtually complete relief; while the other 4 patients, classed as neurotic, admitted partial relief. It is regrettable that the types of headache were not analysed before operation. Usually headache was paroxysmal, and in a few patients it was indistinguishable from migraine; in some cases it lasted for twenty-four hours or more and recurred several times a week; in many it was associated with vomiting. After operation headache which had been troublesome for twenty or thirty years has remained in abeyance for three years or more. We are convinced that this relief of headache is not a psychotherapeutic result. Like the hypertensive headache itself, the relief is unrelated to the blood-pressure after operation, and it is also unrelated to the development or persistence of postural hypotension. It would seem likely that the effects on both headache and on retinopathy (see below) are in some way related to the retention by the craniocerebral vasculature of its innervation; just as vasoconstriction occurs in the upper limbs following dorsolumbar sympathectomy, circulatory readjustments could be expected in the extracranial and intracranial circulations.

Of the 14 male cases with papillœdema (which was usually accompanied by retinal hæmorrhages and exudates), 5 have died either before or very soon after completion of the operation. In 2 patients papillœdema persisted despite Smithwick and Boyd operations, respectively, and each died with uræmia. In 7 other cases papillœdema disappeared. In 5 of the 10 females with papillœdema complete resolution has taken place; 2 died immediately after operation: in 1 papillœdema has persisted despite an "Adson+" operation: in 2 we have no reliable postoperative report on the ocular fundi.

In 8 other females (aged 17–48 years) and 2 males (aged 41 and 43 years) retinal exudates and/or hæmorrhages, present before operation, have disappeared completely; and we have been unable to detect any evidence of recurrence.

As with relief of headache, the favourable change in the optic fundus bears no relation to the postoperative blood-pressure. It has been impressive to see patients some months after operation in whom the diastolic pressure has been 150–160 mm. Hg, yet with papillœdema resolved and crippling headache relieved. We cannot say whether it is necessary to have had postoperative postural hypotension in order to obtain these changes. It is, however, possible to say that the favourable response can persist when any detectable postural hypotension has disappeared. Favourable symptomatic results have followed the Boyd, Smithwick, and "Adson+" operations.

ADVERSE SYMPTOMATIC EFFECTS

Postural hypotension occurred in most patients after operation and was associated with postural tachycardia. In some patients the effect has been detectable for a few months only; in others it has persisted for more than a year. We have noted that in some cases postural tachycardia persists when postural hypotension is no longer detectable. These postural effects have never constituted a therapeutic problem, and any associated symptoms have usually passed off within a few months. In many patients in whom operation has failed to reduce the recumbent blood-pressure there has been an appreciable fall on standing. This effect could conceivably help to account for some of the favourable effects of operation (e.g., on retinopathy) in the "failures." Wilkins et al. (1948) have shown that sympathectomy greatly reduces the reflex vasopressor responses of the hypertensive patient, and claim that this may partly account for favourable changes in the cardiovascular system after operation. A similar claim could be made for postural hypotension. The phenomenon merits further systematic study.

A much more frequent source of postoperative distress has been exertional tachycardia, dyspnœa, and easy fatigability. This has been more prominent in cases submitted to the more extensive Boyd operation.

We might now hesitate to operate on a patient of this kind—free from symptoms, with minimal vascular changes, and a labile blood-pressure falling to 150/105 mm. Hg with bed rest. His hypertension had, however, produced cardiac enlargement, which was reversed by the operation (see fig. 6). Renal-biopsy showed hypertensive vascular changes with widespread hyaline changes in the *afferent arterioles* and *endarteritis fibrosa* of intralobular arteries. The pathologist (Dr. J. Davson) reported that the appearances were those of "essential hypertension probably in malignant phase." We think that the operation was justifiable and that the patient has probably benefited therefrom.

Chronic Atrophic Pyelonephritis

Case 2.—A 17-year-old schoolgirl gave a history of occasional attacks of urinary frequency, asthma for two years, and very severe bilious headaches for six months. There was no family history of hypertensive disease. A physician elsewhere recorded a blood-pressure of 190/110 mm. Hg, and a month later of 250/190.

She was admitted to the surgical unit where, during the next fortnight, the blood-pressure varied between 200/145 and 180/120. We ourselves recorded a pressure of 210/140, and we found a few small exudates between the macula and the temporal margin of the optic disc on both sides. The urine was sterile on culture; renal-function tests were normal, and both kidneys excreted 'Diodrast'; ascending pyelography revealed "distended pelvis and calyces on the right side."

Splanchnicectomy with resection of sympathetic ganglia from D4 to L3 was performed in four stages by Professor Boyd. Examination at operation revealed apparently normal adrenal glands and a "small fibrotic right kidney." Renal biopsy on the right side was reported as follows (*Dr. Davson*). "Glomeruli: normal number present; some show distortion and adhesions; one is in process of fibroblastic obliteration others are normal. Several foci of intense round-cell infiltration are present and there is early fibrosis. Arterioles show arteriosclerosis, and one intralobular shows endarteritis

The postural hypotension corresponding to the given recumbent pressure is shown in parentheses.

rosa. The appearances are those of hypertension with idence of progressive renal damage: chronic pyelonephritis annot be eliminated by examination of a single segment of dney."

The patient left hospital fourteen weeks after admission, ith a blood-pressure of 130/75 mm. Hg and pulse-rate of 4 per min. (recumbent), postural hypotension of 60/40 mm. Ig, and postural tachycardia of 144 per min. Postural iddiness subsided in two months. Subsequent readings btained in the outpatient department were as follows:

Months after operation	Lying B.P. (mm. Hg)	Lying Pulse-rate per min.	Standing B.P. (mm. Hg)	Standing Pulse-rate per min.
5	170/115	96	125/90	112
9	160/105	85	115/80	140
14	145/105	80	145/100	100
19	145/95	88	135/95	128

For some months after operation the patient was subject to more severe asthmatic attacks, and to severe dyspnœa with asthma on exertion. At a year after operation she had few asthmatic attacks, no headaches, and felt well, though she was still easily tired by exertion. The retinal exudates disappeared and have not recurred.

We repeatedly see in young women cases where pyelonephritis is associated with a malignant type of hypertension and with a uræmic termination. We feel convinced that the hypertension itself contributes materially to the development of uræmia, and that in the case recorded above the operative reduction of the blood-pressure from dangerous levels should help to defer indefinitely the development of renal failure. Cases of this type may be the best suited for sympathectomy.

Essential Hypertension

Case 3.—A man, aged 43 years, had suffered from headaches for about a year and had recently developed typical migraine with visual phenomena. Five years ago a systolic pressure of 180 mm. Hg was recorded, and a year ago one of 230 mm. During a month at rest in hospital the systolic blood-pressure varied from 230 to 170 mm. and the diastolic from 150 to 100. Renal function was normal. The heart was slightly enlarged and there were a few small superficial retinal hæmorrhages with fairly well-marked vascular changes. Sympathectomy (D4–L3) was performed by Professor Boyd in three stages, and two weeks after its completion the blood-pressure was 125/90 mm. Hg recumbent and 75/50 standing. When the patient was last seen, two years after the operation, the recumbent pressure was 160/95 falling to 140/95 on standing; he was well and free from symptoms. Blood-pressure readings in this patient are charted in fig. 7.

In this case the result is not so spectacular as in our other "successful" cases; but even here it is significant that a patient who had diastolic pressures of 130–150 mm. at rest in bed now has ambulatory pressures no higher than 110 mm. Hg.

Symptomatic Results

Assessment of the results of operation has so far been confined to its effect on the recumbent blood-pressure. Even when the postoperative blood-pressure remains equal to, or higher than, preoperative levels there may be obvious symptomatic improvement in headaches and retinopathy. On the other hand, whether the operation is a "failure" or "success" from the standpoint of the hypertension, adverse symptoms may be produced, such as postural hypotension and tachycardia, severe exertional tachycardia and fatigability, cold hands or intensification of Raynaud's phenomena, or exacerbation of the asthmatic state. (The effect of the operation on the male sexual function will be reported elsewhere.)

A fair proportion of the most severe cases of hypertension never have headache. Of our patients, 33 who have lived long enough for assessment had significant and often very severe headache before operation: in 29 of these, operation afforded virtually complete relief; while the other 4 patients, classed as neurotic, admitted partial relief. It is regrettable that the types of headache were not analysed before operation. Usually headache was paroxysmal, and in a few patients it was indistinguishable from migraine; in some cases it lasted for twenty-four hours or more and recurred several times a week; in many it was associated with vomiting. After operation headache which had been troublesome for twenty or thirty years has remained in abeyance for three years or more. We are convinced that this relief of headache is not a psychotherapeutic result. Like the hypertensive headache itself, the relief is unrelated to the blood-pressure after operation, and it is also unrelated to the development or persistence of postural hypotension. It would seem likely that the effects on both headache and on retinopathy (see below) are in some way related to the retention by the craniocerebral vasculature of its innervation; just as vasoconstriction occurs in the upper limbs following dorsolumbar sympathectomy, circulatory readjustments could be expected in the extracranial and intracranial circulations.

Of the 14 male cases with papillœdema (which was usually accompanied by retinal hæmorrhages and exudates), 5 have died either before or very soon after completion of the operation. In 2 patients papillœdema persisted despite Smithwick and Boyd operations, respectively, and each died with uræmia. In 7 other cases papillœdema disappeared. In 5 of the 10 females with papillœdema complete resolution has taken place; 2 died immediately after operation: in 1 papillœdema has persisted despite an "Adson+" operation: in 2 we have no reliable postoperative report on the ocular fundi.

In 8 other females (aged 17–48 years) and 2 males (aged 41 and 43 years) retinal exudates and/or hæmorrhages, present before operation, have disappeared completely; and we have been unable to detect any evidence of recurrence.

As with relief of headache, the favourable change in the optic fundus bears no relation to the postoperative blood-pressure. It has been impressive to see patients some months after operation in whom the diastolic pressure has been 150–160 mm. Hg. yet with papillœdema resolved and crippling headache relieved. We cannot say whether it is necessary to have had postoperative postural hypotension in order to obtain these changes. It is, however, possible to say that the favourable response can persist when any detectable postural hypotension has disappeared. Favourable symptomatic results have followed the Boyd, Smithwick, and "Adson+" operations.

ADVERSE SYMPTOMATIC EFFECTS

Postural hypotension occurred in most patients after operation and was associated with postural tachycardia. In some patients the effect has been detectable for a few months only; in others it has persisted for more than a year. We have noted that in some cases postural tachycardia persists when postural hypotension is no longer detectable. These postural effects have never constituted a therapeutic problem, and any associated symptoms have usually passed off within a few months. In many patients in whom operation has failed to reduce the recumbent blood-pressure there has been an appreciable fall on standing. This effect could conceivably help to account for some of the favourable effects of operation (e.g., on retinopathy) in the "failures." Wilkins et al. (1948) have shown that sympathectomy greatly reduces the reflex vasopressor responses of the hypertensive patient, and claim that this may partly account for favourable changes in the cardiovascular system after operation. A similar claim could be made for postural hypotension. The phenomenon merits further systematic study.

A much more frequent source of postoperative distress has been exertional tachycardia, dyspnœa, and easy fatigability. This has been more prominent in cases submitted to the more extensive Boyd operation.

We might now hesitate to operate on a patient of this kind—free from symptoms, with minimal vascular changes, and a labile blood-pressure falling to 150/105 mm. Hg with bed rest. His hypertension had, however, produced cardiac enlargement, which was reversed by the operation (see fig. 6). Renal biopsy showed hypertensive vascular changes with widespread hyaline changes in the afferent arterioles and endarteritis fibrosa of intralobular arteries. The pathologist (Dr. J. Davson) reported that the appearances were those of "essential hypertension probably in malignant phase." We think that the operation was justifiable and that the patient has probably benefited therefrom.

Chronic Atrophic Pyelonephritis

Case 2.—A 17-year-old schoolgirl gave a history of occasional attacks of urinary frequency, asthma for two years, and very severe bilious headaches for six months. There was no family history of hypertensive disease. A physician elsewhere recorded a blood-pressure of 190/110 mm. Hg, and a [illegible] later of 250/190.

She was admitted to the surgical unit where, during the next fortnight, the blood-pressure varied between [illegible] and 180/120. We ourselves recorded a pressure of [illegible] and we found a few small exudates between the macula and the temporal margin of the optic disc on both sides. The urine was sterile on culture; renal-function tests were normal and both kidneys excreted 'Diodrast'; ascending pyelography revealed "distended pelvis and calyces on the right side."

Splanchnicectomy with resection of sympathetic chain from D4 to L3 was performed in four stages by Professor Boyd. Examination at operation revealed apparently normal adrenal glands and a "small fibrotic right kidney." Renal biopsy on the right side was reported as follows (Dr. Davson): "Glomeruli: normal number present; some show distortion and adhesions; one is in process of fibroblastic obliteration; others are normal. Several foci of intense round-cell infiltration are present and there is early fibrosis. Arterioles show arteriosclerosis, and one intralobular shows endarteritis

The postural hypotension corresponding to the given recumbent pressure is shown in parentheses.

in the series of Peet and Isberg (1948) have already been stated.

Smithwick's (1949) most recent assessment of his results suggests that sympathectomy does not much influence the prognosis of malignant hypertension, though all agree that retinopathy and headache can usually be improved. Where operation can be expeditiously performed it is certainly worth while if for the rest of his life the patient is protected from blindness and rendered comfortably free from headache: but this group of cases has the highest operative mortality (Peet and Isberg 1948). We shall continue to use the operation in selected cases in an attempt to preserve vision. We remain open-minded about the effect of operation on prognosis.

The final consideration is whether operation is justified in an attempt to relieve severe headache alone. Those of our patients who had suffered incapacitating headaches previously are emphatic in their assertion that it is worth while. It is particularly impressive to be told by a 50-year-old woman, who has had four operations and spent a week in an oxygen-tent with nearly fatal pulmonary œdema, that she would go through it all again for the relief that it has afforded. The same patient takes small account of the fact that, whereas she could do full housework before the operation, she now does virtually none on account of exertional tachycardia and fatigability. We conclude that sympathectomy may be justifiable as a symptomatic measure for the relief of crippling headache: but in a few patients relief may be bought at the price of new symptoms. In cases of this kind it would be useful to know what is the least surgical procedure compatible with relief.

We set out originally to assess the merits of the more extensive Boyd operation, as compared with the Smithwick operation, in the reduction of blood-pressure. Our "successful" cases are so few as to make this impossible. Symptomatic relief is about the same in both (and in the "Adson +"), but the more extensive operation appears to produce more often symptoms of exertional tachycardia and fatigue; we are not much encouraged to continue with it. It is not our intention to become surgical apologists, nor to guess whether accessory sympathetic ganglia, such as those described by Boyd and Monro (1949), or nerve degeneration could be responsible for our failures. All we can say is that sympathectomy, as now performed by competent surgeons, has a very limited rôle in the treatment of hypertensive disease.

SUMMARY

The results of sympathectomy in 80 cases of hypertension are presented and discussed.

Many of the good results recorded by others are attributed to inadequate appreciation of the benign and variable course of mild hypertension.

In this series only cases in which the prognosis was judged to be unfavourable—usually with resting diastolic blood-pressures of 120 mm. Hg or more—have been subjected to operation.

In only 11 of 80 cases was a significant and lasting reduction of blood-pressure achieved. Most of these cases were young women, under 40 years of age, suffering either from essential hypertension or from renal hypertension with good renal function.

Headache and retinopathy are sometimes relieved by a sympathectomy which has failed to reduce blood-pressure.

Sympathectomy should very rarely be advised in hypertensive disease. Some of the indications are defined.

We should like again to express our appreciation of the work done in this study by Prof. A. M. Boyd and his surgical team, and also to thank our medical colleagues for permission to follow up some of their cases after operation.

THE RELATION OF PROPHYLACTIC INOCULATIONS TO THE ONSET OF POLIOMYELITIS

BERTRAM P. MCCLOSKEY
M.B. Melb.

POLIOMYELITIS OFFICER, STATE HEALTH DEPARTMENT,
MELBOURNE, VICTORIA, AUSTRALIA

AN epidemic of poliomyelitis commenced in Melbourne, Victoria, in January of 1949, and later spread to the country areas of the State of Victoria and to the adjoining State of South Australia (July–August). The incidence in the other States of Australia was low during this period. The epidemic in Victoria is now subsiding.

Early in the epidemic, attention was directed to a few patients who had been given an injection of pertussis vaccine, or of a mixture of diphtheria toxoid and pertussis vaccine, shortly before the onset of their symptoms. The parents of these children were naturally inclined to blame the inoculations for the development of the disease, though their medical attendants either dismissed the possibility of any causal relationship or else considered the effects to be due to a radiculitis caused by the vaccine. It was decided to inquire for a history of immunisation in the course of a routine investigation of reported cases: though any real association between inoculation and poliomyelitis infection was then considered highly improbable. Considerable evidence, however, will be presented to show that such an association has existed in this epidemic.

METHOD OF INQUIRY

There were 375 cases of poliomyelitis notified in Victoria from January to August, 1949. The parents of 340 of these cases were asked whether the child had ever been immunised against diphtheria or whooping-cough, and, if so, the date and the doctor's name. The remaining 35 cases reported during this period could not be similarly investigated, either because of inaccessibility of the patient, or of inability to contact the parents. No selection of cases whose parents were interviewed was made, and every effort was made to interview the parents of every case reported, but in 35 cases this proved impossible.

Of those cases investigated, if any inoculation had been given within three months of the onset, I personally obtained particulars from the parents of the exact dates and of the sites of all inoculations. I then checked the parents' statements with the doctor's records. Occasionally the parents were uncertain of the exact date or site. In only 4 cases confirmation of the parents' statements as to date and site could not be obtained from the doctor. The data of these 4 cases were recorded as doubtful, and they have been excluded from consideration.

Patients with perfect exercise tolerance before operation find themselves incommoded by stairs and unable to hurry. They adjust by curtailing their activity, and if operation has relieved distressing headaches will often make no complaint of the adverse symptoms.

Two patients with Raynaud's syndrome before operation have complained of an intensification of symptoms after dorsolumbar sympathectomy; and in one, phenol injection of the stellate ganglia was later performed in another hospital. Many other patients note cold hands. In two patients previous asthmatic symptoms were intensified; and in one asthma developed de novo after operation. These adverse effects were of relatively short duration. Other minor sequelæ included loss of ejaculation, and neuralgia in relation to the incisions, the latter particularly after rib resection.

Although these postoperative sequelæ may be distressing, the patient usually regards the operation as worth while if it has removed his headache or improved his vision. If, on the other hand, these develop in a patient, previously symptom-free, for whom operation was recommended merely with a view to reducing a dangerously high diastolic pressure, the patient is likely to be dissatisfied with the result. These points should be borne in mind when sympathectomy is contemplated.

DISCUSSION

The results presented may appear surprising in the light of other reports which enthusiastically endorse the belief that sympathectomy is effective in reducing blood-pressure. The valuable and highly critical survey by Evelyn et al. (1949) of cases submitted to sympathectomy at the Massachusetts General Hospital has, however, shown that "successful" results after five years can be anticipated in no more than 20% of cases. Their material must consist largely of cases previously reviewed by Smithwick at the same hospital; and Smithwick (1944) has made it clear that some of his operations were on patients with resting diastolic pressures as low as 100 mm. Hg, or even below 90. The Boston series with its 20% of favourable results in five years is thus in no way comparable with the present series.

Before attempting to derive any guiding principles from our cases, it is advisable to summarise the results. A significant reduction of blood-pressure has been achieved in 11 of our 80 cases, and the follow-up period has been relatively short. At least 12 cases of malignant hypertension have lost their papillœdema without any appreciable change in blood-pressure; 10 other patients have rapidly lost retinal hæmorrhages or exudates after operation, and 7 of these showed no change in blood-pressure. Nearly all surviving patients who had suffered from severe headache have obtained relief. A few cases of malignant hypertension have died as a result of operation, and some patients have exchanged severe headache for severe exertional tachycardia and fatigability.

The following remarks and suggestions are intended as guidance for the physician whose difficult business it is to decide whether or not sympathectomy should be considered in the management of *a particular case* of hypertensive disease. We are not concerned with the formulation of intricate rules which might enable the surgeon to achieve a good, but possibly academic, score of "successes." Our aim is rather to give, from a consideration of our own results and those previously reported, our clinical advice on the possible indications for, and probable outcome of, sympathectomy in hypertensive disease.

The responsibility for submitting patients to operation should remain with the physician, who must realise two important facts:

1. Hypertension per se may be too mild to warrant operation. There is no evidence whatever that a symptom-free case of essential hypertension with a diastolic pressure of 115 mm. Hg or less would be better prognostically if the pressure were reduced to 80–90 mm. by surgery.

2. If the blood-pressure itself is the physician's concern, he has little chance of changing it significantly by operation in patients of either sex if they are over the age of 45, whether the hypertension be moderate, severe, or "malignant."

The physician must therefore be ready to dismiss the idea of sympathectomy in most cases of essential hypertension. Patients over the age of 45 years (especially male); patients with large-vessel sclerosis, angina pectoris, or myocardial infarction; patients with congestive cardiac failure or renal failure; and patients who have had more than one cerebral thrombosis—none of these should be submitted to operation for hypertension. There is little evidence that sympathectomy benefits them at all, and the risks are great.

Some patients with essential hypertension—often in the late thirties or early forties—develop exertional dyspnœa and are found clinically to have a somewhat enlarged heart and little else amiss. We hold that such cases should be managed on the general lines of restricted activity, sedation, weight reduction, and reduced intake of salt. If this is impracticable or unsuccessful, sympathectomy may be considered, since, as our own case 3 and other reports show, some successes may be achieved. The other group of cases in which we think that sympathectomy may be helpful is that of severe hypertension in young adults. Such cases may be "essential" or clearly secondary to a renal lesion such as pyelonephritis or type-1 nephritis. If the nephropathy is active and progressive, no help is to be expected from sympathectomy, as is shown by the report of Reyersbach and Butler (1949) on the operation in children with nephritis. If the renal lesion is inactive, renal function remains good, and the diastolic pressure is 125–150 mm. Hg, sympathectomy is indicated and we would submit the patient to operation whether or not the hypertension had entered the "malignant" phase (see cases 2, 4, 6, and 9). It appears that useful results may be expected, especially in females below the age of 40 years. If the young adult is thought to have *essential* hypertension, much more thought and care is necessary in arriving at the decision to operate. In almost all such cases it is justifiable to postpone one's decision for months or even a year or two; the decision to operate may then be made because the diastolic pressure remains consistently high (125–140 mm. Hg); because the patient has severe symptoms such as headache, which would be relieved by operation; or because a cerebral episode has occurred (cases 9 and 10) and it is thought that a further episode would be less likely if the blood-pressure were lower.

A word of warning is perhaps necessary in view of the report by Reyersbach and Butler (1949) of sympathectomy in children aged 7 and 13 years with so-called essential hypertension. In one of these we would question the diagnosis, though we agree that symptomless essential hypertension may occur in adolescence; one of us (S. W. S.) has seen eclampsia grafted on to essential hypertension at the age of 14 years. Little is known, however, of the disease in children, of the spontaneous changes in their blood-pressure, and of the pressor effect on them of the doctor and his sphygmomanometer; and we would under no circumstances submit children to sympathectomy on the strength of blood-pressure readings alone.

We find it difficult to give a final opinion on sympathectomy in the malignant type of hypertension. We have already said that we do not regard the malignant phase as a contra-indication to operation in young adults with renal hypertension. Our experiences with malignant essential hypertension have not been encouraging. Others (Poppen and Lemmon 1947, Palmer 1947, Peet and Isberg 1948) are more enthusiastic. Certain objections the series of Peet and Isberg (1948) have already en stated.

Smithwick's (1949) most recent assessment of his sults suggests that sympathectomy does not much fluence the prognosis of malignant hypertension, though l agree that retinopathy and headache can usually be proved. Where operation can be expeditiously perrmed it is certainly worth while if for the rest of his e the patient is protected from blindness and rendered mfortably free from headache: but this group of cases as the highest operative mortality (Peet and Isberg 948). We shall continue to use the operation in selected ases in an attempt to preserve vision. We remain pen-minded about the effect of operation on prognosis.

The final consideration is whether operation is justified n an attempt to relieve severe headache alone. Those of ur patients who had suffered incapacitating headaches reviously are emphatic in their assertion that it is worth while. It is particularly impressive to be told by a 0-year-old woman, who has had four operations and pent a week in an oxygen-tent with nearly fatal pulmonary œdema, that she would go through it all again or the relief that it has afforded. The same patient akes small account of the fact that, whereas she could do full housework before the operation, she now does virtually none on account of exertional tachycardia and fatigability. We conclude that sympathectomy may be ustifiable as a symptomatic measure for the relief of crippling headache: but in a few patients relief may be bought at the price of new symptoms. In cases of this kind it would be useful to know what is the least surgical procedure compatible with relief.

We set out originally to assess the merits of the more extensive Boyd operation, as compared with the Smithwick operation, in the reduction of blood-pressure. Our "successful" cases are so few as to make this impossible. Symptomatic relief is about the same in both (and in the "Adson +"), but the more extensive operation appears to produce more often symptoms of exertional tachycardia and fatigue; we are not much encouraged to continue with it. It is not our intention to become surgical apologists, nor to guess whether accessory sympathetic ganglia, such as those described by Boyd and Monro (1949), or nerve degeneration could be responsible for our failures. All we can say is that sympathectomy, as now performed by competent surgeons, has a very limited rôle in the treatment of hypertensive disease.

SUMMARY

The results of sympathectomy in 80 cases of hypertension are presented and discussed.

Many of the good results recorded by others are attributed to inadequate appreciation of the benign and variable course of mild hypertension.

In this series only cases in which the prognosis was judged to be unfavourable—usually with resting diastolic blood-pressures of 120 mm. Hg or more—have been subjected to operation.

In only 11 of 80 cases was a significant and lasting reduction of blood-pressure achieved. Most of these cases were young women, under 40 years of age, suffering either from essential hypertension or from renal hypertension with good renal function.

Headache and retinopathy are sometimes relieved by a sympathectomy which has failed to reduce blood-pressure.

Sympathectomy should very rarely be advised in hypertensive disease. Some of the indications are defined.

We should like again to express our appreciation of the work done in this study by Prof. A. M. Boyd and his surgical team, and also to thank our medical colleagues for permission to follow up some of their cases after operation.

DIAGNOSIS

Of the 375 cases of poliomyelitis reported, 340 were investigated: about 250 of them, including every case of which the particulars are presented in the tables, were fully investigated by me personally. Most of them were admitted to the Infectious Diseases Hospital, Fairfield, Melbourne, where the diagnosis was confirmed by the experienced medical staff. Many were also seen by members of the panel of consultant physicians, appointed by the Consultative Council on Poliomyelitis of this State. Clinically, the cases associated with recent immunisation were indistinguishable from the remaining acute cases of paralytic poliomyelitis seen during this period. Of the patients included in table I, only 1 (no. 161) was not paralysed, a female child aged sixteen months. Her clinical picture was consistent with non-paralytic poliomyelitis. On admission to hospital her cerebrospinal fluid contained 65 leucocytes per c.mm. (70% polymorphs, 30% lymphocytes), and its protein content was 60 mg. per 100 ml.

TABLE I—FINDINGS IN 31 CHILDREN INOCULATED WITHIN THREE MONTHS OF ONSET

	Total	6	7	8	19	40

ASSESSMENT OF THE SITE OF PARALYSIS AND ITS SEVERITY

The sites of paralysis were determined at the initial examination, or at one shortly after the diagnosis had been made. In the majority of these cases, the extent of paralysis of each extremity was initially assessed by me according to the standard scale of the Australian Association of Physiotherapists. The patients whom I did not initially examine were assessed by members of the staff of the Infectious Diseases Hospital, Fairfield. For the sake of uniformity of presentation, both series have been converted to the following scale:

Very severe	(****)	Complete flaccid paralysis.
Severe ..	(***)	Complete paralysis of at least one muscle group.
Moderate ..	(**)	Partial paralysis of at least one muscle group, sufficient to prevent movement of the involved joint against gravity.
Mild .. .	(*)	Lesser degrees of paralysis, permitting movement against gravity.
Nil ..	(0)	No detectable paralysis of an extremity.

These findings were, in all cases whose particulars are included in this paper, compared with those of the physiotherapists treating the cases and were found to correspond exactly.

It is emphasised that the inquiry into the site and degree of paralysis always preceded the inquiry as to the site of inoculation. This procedure seems sufficient to ensure against any possibility of bias on the writer's part in the assessment of the site and severity of the paralysis.

FINDINGS

Table I summarises the relevant data of all 31 patients who have received an injection of diphtheria toxoid or pertussis vaccine, alone or in combination, within three months of the onset of symptoms, for whom exact information on date and site of injection could be obtained. The findings in the 4 patients where some degree of doubt existed as to date and site have been omitted. There were no other cases in the 340 investigated in whom a history of an inoculation of diphtheria toxoid and/or pertussis vaccine within three months of the onset was obtained.

RELATION OF THE SITE OF INOCULATION TO SITE OF PARALYSIS

The data in table I on relation of site of inoculation (at any time up to three months before the onset) to site of paralysis are collected in table II.

Paralysis is distinctly more frequent in the inoculated than in the uninoculated extremities in those cases which ived pertussis vaccine either alone or in combination. he patients given only diphtheria toxoid, a difference the incidence of paralysis in the inoculated and ioculated extremities is also evident if we compare corresponding extremities (the arms), though this erence is not as striking as when pertussis vaccine used alone.

'he difference in incidence of paralysis in inoculated uninoculated limbs is so great when pertussis vaccine, ie or combined, has been employed, that an exact tistical assessment of significance, which presents some iculties, hardly appears to be necessary. The cases olving diphtheria toxoid alone are few and it is ibtful whether their statistical assessment would be fitable.

IMMUNISATION HISTORY OF ALL CASES INVESTIGATED

)f the 340 cases investigated a history of previous munisation against whooping-cough and/or diphtheria s obtained in 211. Of these, 65 received inoculations hin one year of the onset of their poliomyelitis. ese results are expressed in table III.

TABLE III

Agent	Period preceding onset in which inoculation was received (all cases)		
	Under 3 months	Between 3 months and 12 months	More than 1 year
P	6	3	9
PD	15	8	51
D	10	19	61
Unknown	4	0	25
Total ..	35	30	146

the remaining 129 cases no history of any immunising ocedure against whooping-cough or diphtheria at any riod of the patient's life was obtained.

Of the 340 cases investigated, 69 were children under ree years of age. The immunisation history of these ildren regarding pertussis and diphtheria is contained table IV.

INTERVAL BETWEEN INJECTION AND DEVELOPMENT OF SYMPTOMS

Table I includes all persons who had received a pro- ıylactic inoculation of one of the three agents within ıree months of the onset of symptoms. It would be xpected that the number of inoculations would be the me in each month. That is far from the case, as appears om table V (extracted from table I).

In this table every inoculation received by each subject ithin ninety days of the onset is included: many ıtients, of course, received multiple injections in that eriod.

It is clear that the more recent the injection of any gent, the more likely is its association with the onset of oliomyelitis. This association can be assessed by the χ^2 test, and is significant for diphtheria toxoid alone, as well as for pertussis vaccine, alone or in combination.

TABLE IV

Agent	Period preceding onset in which last inoculation was received (children under 3)		
	Under 3 months	Between 3 months and 12 months	More than 1 year

Total ..	38	14	3

INTERVAL BETWEEN THE LAST INJECTION AND ONSET OF SYMPTOMS AND SITE OF PARALYSIS

Many patients received more than one injection. Inspection of the data revealed that the last injection before the onset of symptoms was that usually associated with the location of paralysis. The data are arranged in table I to indicate this relationship.

The fourth column in table I shows the intervals, arranged in order of magnitude, between the last injection (excluding three injections given the day before onset) and the onset of symptoms. The incidence of paralysis in limbs receiving the last injections is shown in the sixth, and that in the other limbs in the next four columns. When pertussis vaccine was used, alone or in combination, 22 of 24 limbs receiving the last inoculation were paralysed, and only 16 of the 60 limbs inoculated prior to this or uninoculated were affected. There is less evidence of localisation in the limb last injected when diphtheria toxoid was used; 4 of 11 of the last inoculated limbs were paralysed, and 10 of 29 of the remainder.

INTERVAL BETWEEN THE LAST INOCULATION AND THE ONSET OF SYMPTOMS

The intervals from the last inoculation before the onset of symptoms to that onset ranged from five to thirty-two days, except in 2 patients in whom this interval was approximately sixty days. These 2 patients received diphtheria toxoid, the limbs injected were not paralysed, and it is quite likely that in them the injections were not related to the attacks of poliomyelitis but were coincidental.

TABLE VI—SEVERITY OF PARALYSIS IN LIMBS INOCULATED WITH PERTUSSIS VACCINE WITHIN 35 DAYS AND IN CONTROLS (CHILDREN UNDER 3)

	Immunised group * (15 cases)					Control group * (48 cases)

* For definition of these groups see text.

In poliomyelitis following tonsillectomy, the intervals between the operation and onset of symptoms have ranged from three to thirty days. The literature is summarised by Horstmann and Paul (1947). Leake (1935) reported 12 instances in which an attack of poliomyelitis closely followed administration of a poliomyelitis virus vaccine. Of these 12, 6 children had a single dose two days or less before onset of symptoms. Discarding these very short intervals as unlikely incubation periods, the intervals from injection to onset were seven to fourteen days, as in the majority of cases (19 of 30) in this series. In Leake's series also there was a marked, but not invariable, association between site of inoculation and site of paralysis.

The incubation period of poliomyelitis itself is usually regarded as lying within these same limits, five to thirty days.

RELATION OF INOCULATION TO PARALYSIS IN THE CASES UNDER THREE YEARS OF AGE

In the 17 cases under three years of age receiving pertussis vaccine either alone or in combination within thirty-five days of the onset, full data are available for 16; in 15 paralysis followed in the limb last inoculated before the onset. The paralysis in the limb last inoculated in these cases is shown in table VI.

By contrast the degree of paralysis in each limb of a control group of all children under three (48 in all), notified during the same period as the above 17 cases, who had not received any inoculation within thirty-five days of the onset, and for whom exact information as to the site and severity of paralysis was ascertained, is also shown in table VI.

It is clear that there is a considerable increase in the severity of the paralysis in the last-inoculated limbs of those children under three who received an injection of pertussis vaccine within thirty-five days of the onset of poliomyelitis.

ADMINISTRATIVE ACTION

A report was submitted to the Chief Health Officer (Dr. G. E. Cole) on July 20, 1949, and it was decided to defer action until further evidence had been collected. When this had been done, the Chief Health Officer, in September, 1949, invited Prof. F. M. Burnet, F.R.S., Dr. E. V. Keogh, of the Commonwealth Serum Laboratories, and Dr. H. McLorinan, superintendent of the Infectious Diseases Hospital, Fairfield, to confer with him and officers of his department. It was agreed that there was certainly evidence of some association between prophylactic injections and development of poliomyelitis in the epidemic. This raised questions of great importance from the viewpoint of public-health administration. It was feared that immunisation, particularly against diphtheria, might be prejudiced if the public were informed. The Chief Health Officer, therefore, laid the facts and the opinions of this expert committee before the Consultative Council on Poliomyelitis of the State of Victoria for an opinion whether or not the medical profession and the public should be informed. The council recommended that doctors be advised to discontinue the use of pertussis vaccine during the currency of the epidemic, just as tonsillectomy had been postponed since it appeared to determine an attack of poliomyelitis in rare instances. They also thought that the public should be informed of the facts in regard to pertussis vaccine, alone and in combination. Similar action as regards diphtheria immunisation was considered unnecessary, (1) because the evidence was less certain, and (2) because temporary cessation of mass diphtheria immunisation could readily be arranged.

On Oct. 4, 1949, the Commonwealth Government and the Department of Health in each State were informed of the Victorian findings by the Chief Health Officer acting on the advice of the council. A circular letter was also addressed to all doctors in Victoria, informing them of the position, and a brief statement was issued to the press. The announcements caused no unfavourable press comment; so there is no reason to suppose that the future of immunisation in Victoria has been prejudiced.

DISCUSSION

Evidence has been presented which indicates that an injection of pertussis vaccine, given during an epidemic of poliomyelitis, may determine the onset of paralysis in the immunised child. The evidence that an injection of diphtheria toxoid may have similar effects is, perhaps, less conclusive.

In discussing various possible explanations of the phenomenon, attention will first be directed to the instances in which localisation in the inoculated limb was the prominent feature, following administration of pertussis vaccine, alone or combined.

Any suggestion that the prophylactic agents, on release by the makers, were contaminated with poliomyelitis virus seems highly improbable. No single batch of any one product could be incriminated. The products were made by three different firms—one English, one American, and one Australian. The same immunising agents have been used throughout Australia, but their injection was followed by paralysis only in Victoria, during a severe epidemic of poliomyelitis. Any harmful effects were therefore associated, not with their origin, but with the epidemic prevalence of poliomyelitis.

The chances of syringe transmission have to be considered. The possibility exists of contamination of the hypodermic needle with virus from the doctor's hands or the patient's skin. Or a syringe used to give, for example, penicillin to a child with an undiagnosed fever, which was in reality a non-paralytic attack of poliomyelitis, might later be employed without adequate sterilisation to give a vaccine to another child. But it has also then to be assumed, either that a viræmia occurs in non-paralytic cases, and that the injection of penicillin or other drugs coincides with the viræmia, or that virus is present for a longer or shorter time in the subcutaneous tissues. And since these injections are not intravenous, the chances of contamination of the interior of the syringe would be relatively slight, even if the needle did pierce tissues in which virus was present.

Allowing that local tissue damage caused by the vaccine might favour the successful implantation of a very small dose of virus, these foregoing assumptions are not in harmony with current views of poliomyelitis.

It is conceivable that, in a subject suffering a non-paralytic infection, circulating virus might be arrested and concentrated in tissue damaged by the vaccine, and then travel, perhaps after multiplication, via the peripheral nerves or some other channel, to the corresponding areas in the cord. Again it is necessary to postulate a viræmia and also that the injection itself is given during the period of viræmia, or that the viræmia occurs before the damage done by the vaccine has been repaired.

The final hypothesis to be considered is that proposed by Horstmann and Paul (1947) in explanation of the effect of exercise and other traumata on the development of paralysis. They suggest that local trauma may be reflected in corresponding areas in the cord in the form of central changes, which favour activation of virus already present in the central nervous system. Although the nature of the presumed mechanism is somewhat obscure, the suggestion seems applicable to the present observations, since it merely adds injection of pertussis vaccine to the list of known traumata which influence unfavourably the course of an infection with poliomyelitis virus. But Levison et al. (1945), in experiments on rhesus monkeys, found that trauma to the muscles of an extremity did not influence the site or extent of paralysis, though exercise to the fatigue-point and chilling in the prodromal period had a pronounced effect. These workers injured the tissues by bruising with hammer blows; it is possible that the type of injury may be decisive, and that pertussis vaccine may specifically favour localisation.

None of the hypotheses considered provides a convincing explanation of the observations. Further information, some of which should be obtainable by perimental procedures, is required. It would obviously of interest to determine whether pertussis vaccine roduced intramuscularly can modify the course of e experimental infection in the monkey. Two lines inquiry might be profitable: (1) to see whether, monkeys infected by the intranasal or oral routes, subsequent or coincident injection of pertussis vaccine n determine paralysis of the injected limb; and (2) to termine whether a minimal dose of virus, non-infective r the intramuscular route, may become infective if ven mixed with pertussis vaccine.

The differences observed between the effects of pertussis ccine and diphtheria toxoid are in harmony with e presumption that local damage to tissue is a deter-ining factor. Since the local damage following the jection of pertussis vaccine, or combined pertussis-iphtheria prophylactic, is much more severe than that sually following diphtheria toxoid alone, one would spect more striking and frequent effects to follow dministration of pertussis vaccine, even if, as is the ase in Victoria, many more children are immunised gainst diphtheria.

In considering, however, the frequency and severity of he effects of pertussis vaccine, in comparison with iphtheria toxoid, it should be remembered that pertussis accine is usually given early in the child's life, while iphtheria prophylaxis is often postponed until the child s four or five, and about to enter school. The average ge of the children in this series given pertussis vaccine, lone or in combination, was 2·4 years, and of those eceiving diphtheria toxoid 5·1 years. Location of the paralysis in the injected limb may be, therefore, a phenomenon more likely to occur in younger children, rrespective of the nature of the prophylactic agent.

One further point remains to be mentioned. A nursing sister developed typical poliomyelitis after an injection of typhoid-paratyphoid vaccine into the left upper arm. Ten days after the injection she felt unwell and remained in bed for two days. She returned to duty, but on the thirteenth day developed general muscle pains and vomiting. She developed considerable weakness in the injected left arm and in both legs. Another nursing sister who received a similar inoculation at the same time became ill after the same interval and was diagnosed as suffering from poliomyelitis. She was not, however, reported as a case, and no further details are available.

SUMMARY

Evidence is presented that in the current epidemic of poliomyelitis in Victoria there has been a relation, in a number of cases, between an injection of an immunising agent and the subsequent development of paralytic poliomyelitis.

I am indebted to the Chairman of the Health Commission of Victoria, Dr. G. E. Cole, for permission to publish this paper.

I wish to acknowledge gratefully the encouragement and guidance given me by Dr. E. V. Keogh throughout this investigation, and his help in the preparation of this paper. Also I wish to thank Dame Jean Macnamara (who is a constant inspiration to workers in the poliomyelitis field in Australia); Dr. H. McLorinan for his courtesy in giving me access to the patients and their records in the Infectious Diseases Hospital, Fairfield; Mr. Alwyn Mathew of the Commonwealth Serum Laboratories, Melbourne; and Dr. H. O. Lancaster of the School for Public Health and Tropical Medicine, University of Sydney, for statistical advice. Finally, I wish to thank the staff of the Health Department in Victoria who have so willingly assisted me in my investigations.

FIRST ASSISTANT TO THE NUFFIELD PROFESSOR OF CLINICAL MEDICINE, OXFORD

ULCERATIVE colitis varies so widely in its severity and course that the prognosis is uncertain and the assessment of new treatments is correspondingly difficult. We have investigated in a series of cases some of the factors which may influence the course of the disease and thus have prognostic significance.

MATERIAL AND METHOD

In the eleven years 1938–48 inclusive, 129 patients were treated for ulcerative colitis in the Radcliffe Infirmary. We have analysed their case-records and followed their progress. The follow-up was conducted initially by post and later at a special outpatient clinic for those still living in the area. The response to inquiry was satisfactory, 121 out of the 129 being traced.

A representative unbiased sample of patients must be studied if one is to get a clear idea of the prognosis in any disease. With a chronic and relapsing disease such as this, the total admissions to a hospital include many patients who have previously been treated in other hospitals. A disease may be more lethal in its early than in its later stages, or vice versa. Hence we have divided the patients into two groups:

New cases: 72 patients in whom ulcerative colitis had been present for less than two years before their first admission to the Radcliffe Infirmary and who had had no previous hospital treatment elsewhere.

Old cases: all other patients.

The time limit of two years was set to exclude from the new cases a few patients with the chronic continuous type of ulcerative colitis who had had diarrhœa for years before their first admission to the Radcliffe Infirmary but had not been treated in another hospital.

For the reasons given above we have concerned ourselves mainly with the 72 new cases so far as prognosis is concerned.

RESULTS

Age and Sex

Ulcerative colitis occurs chiefly in the first half of adult life. More than half of the present patients began their illness in their twenties or thirties. The disease may, however, arise at any age after infancy, though rarely before the 'teens or after the fifties. The youngest patient in this series was 5 years old and the oldest 68.

Ulcerative colitis affects both sexes, but different series have yielded very different proportions of males and females. Thus Hern (1931), Buzzard et al. (1938), and Cullinan (1938) had about twice as many women as men in their series, whereas Hardy and Bulmer (1933) and Willard et al. (1938) had roughly equal numbers of men and women. Our series contains nearly twice as many women as men, as follows:

Age-group (years)	*Male*	*Female*	*Total*
0–9	2	1	3
10–19	3	8	11
20–29	12	22	34
30–39	15	24	39
40–49	9	13	22
50–59	3	10	13
60–69	3	4	7
Totals	47	82	129

This sex difference may be partly due to the influence of war, with the removal from the civilian population of a high proportion of men of the most susceptible ages. This view gains support from the numbers of admissions in the war years and in the non-war years, as follows:

	Females	*Males*
Non-war years	29	25
War years (1940–45)	50	21

association between site of inoculation and site of paralysis.

The incubation period of poliomyelitis itself is usually regarded as lying within these same limits, five to thirty days.

RELATION OF INOCULATION TO PARALYSIS IN THE CASES UNDER THREE YEARS OF AGE

In the 17 cases under three years of age receiving pertussis vaccine either alone or in combination within thirty-five days of the onset, full data are available for 16; in 15 paralysis followed in the limb last inoculated before the onset. The paralysis in the limb last inoculated in these cases is shown in table VI.

By contrast the degree of paralysis in each limb of a control group of all children under three (48 in all), notified during the same period as the above 17 cases, who had not received any inoculation within thirty-five days of the onset, and for whom exact information as to the site and severity of paralysis was ascertained, is also shown in table VI.

It is clear that there is a considerable increase in the severity of the paralysis in the last-inoculated limbs of those children under three who received an injection of pertussis vaccine within thirty-five days of the onset of poliomyelitis.

ADMINISTRATIVE ACTION

A report was submitted to the Chief Health Officer (Dr. G. E. Cole) on July 20, 1949, and it was decided to defer action until further evidence had been collected. When this had been done, the Chief Health Officer, in September, 1949, invited Prof. F. M. Burnet, F.R.S., Dr. E. V. Keogh, of the Commonwealth Serum Laboratories, and Dr. H. McLorinan, superintendent of the Infectious Diseases Hospital, Fairfield, to confer with him and officers of his department. It was agreed that there was certainly evidence of some association between prophylactic injections and development of poliomyelitis in the epidemic. This raised questions of great importance from the viewpoint of public-health administration. It was feared that immunisation, particularly against diphtheria, might be prejudiced if the public were informed. The Chief Health Officer, therefore, laid the facts and the opinions of this expert committee before the Consultative Council on Poliomyelitis of the State of Victoria for an opinion whether or not the medical profession and the public should be informed. The council recommended that doctors be advised to discontinue the use of pertussis vaccine during the currency of the epidemic, just as tonsillectomy had been postponed since it appeared to determine an attack of poliomyelitis in rare instances. They also thought that the public should be informed of the facts in regard to pertussis vaccine, alone and in combination. Similar action as regards diphtheria immunisation was considered unnecessary, (1) because the evidence was less certain, and (2) because temporary cessation of mass diphtheria immunisation could readily be arranged.

On Oct. 4, 1949, the Commonwealth Government and the Department of Health in each State were informed of the Victorian findings by the Chief Health Officer acting on the advice of the council. A circular letter was also addressed to all doctors in Victoria, informing them of the position, and a brief statement was issued to the press. The announcements caused no unfavourable press comment; so there is no reason to suppose that the future of immunisation in Victoria has been prejudiced.

DISCUSSION

Evidence has been presented which indicates that an injection of pertussis vaccine, given during an epidemic of poliomyelitis, may determine the onset of paralysis in the immunised child. The evidence that an injection diphtheria toxoid may have similar effects is, perhaps less conclusive.

In discussing various possible explanations of the phenomenon, attention will first be directed to the instances in which localisation in the inoculated limb was the prominent feature, following administration of pertussis vaccine, alone or combined.

Any suggestion that the prophylactic agents, on release by the makers, were contaminated with poliomyelitis virus seems highly improbable. No single batch of any one product could be incriminated. The products were made by three different firms—one English, one American, and one Australian. The same immunising agents have been used throughout Australia, but their injection was followed by paralysis only in Victoria during a severe epidemic of poliomyelitis. Any harmful effects were therefore associated, not with their origin, but with the epidemic prevalence of poliomyelitis.

The chances of syringe transmission have to be considered. The possibility exists of contamination of the hypodermic needle with virus from the doctor's hands or the patient's skin. Or a syringe used to give, for example, penicillin to a child with an undiagnosed fever, which was in reality a non-paralytic attack of poliomyelitis, might later be employed without adequate sterilisation to give a vaccine to another child. But it has also then to be assumed, either that a viræmia occurs in non-paralytic cases, and that the injection of penicillin or other drugs coincides with the viræmia, or that virus is present for a longer or shorter time in the subcutaneous tissues. And since these injections are not intravenous, the chances of contamination of the interior of the syringe would be relatively slight, even if the needle did pierce tissues in which virus was present.

Allowing that local tissue damage caused by the vaccine might favour the successful implantation of a very small dose of virus, these foregoing assumptions are not in harmony with current views of poliomyelitis.

It is conceivable that, in a subject suffering a non-paralytic infection, circulating virus might be arrested and concentrated in tissue damaged by the vaccine, and then travel, perhaps after multiplication, via the peripheral nerves or some other channel, to the corresponding areas in the cord. Again it is necessary to postulate a viræmia and also that the injection itself is given during the period of viræmia, or that the viræmia occurs before the damage done by the vaccine has been repaired.

The final hypothesis to be considered is that proposed by Horstmann and Paul (1947) in explanation of the effect of exercise and other traumata on the development of paralysis. They suggest that local trauma may be reflected in corresponding areas in the cord in the form of central changes, which favour activation of virus already present in the central nervous system. Although the nature of the presumed mechanism is somewhat obscure, the suggestion seems applicable to the present observations, since it merely adds injection of pertussis vaccine to the list of known traumata which influence unfavourably the course of an infection with poliomyelitis virus. But Levison et al. (1945), in experiments on rhesus monkeys, found that trauma to the muscles of an extremity did not influence the site or extent of paralysis, though exercise to the fatigue-point and chilling in the prodromal period had a pronounced effect. These workers injured the tissues by bruising with hammer blows; it is possible that the type of injury may be decisive, and that pertussis vaccine may specifically favour localisation.

None of the hypotheses considered provides a convincing explanation of the observations. Further information, some of which should be obtainable by imental procedures, is required. It would obviously [interest to determine whether pertussis vaccine duced intramuscularly can modify the course of experimental infection in the monkey. Two lines iquiry might be profitable: (1) to see whether, onkeys infected by the intranasal or oral routes, bsequent or coincident injection of pertussis vaccine determine paralysis of the injected limb; and (2) to rmine whether a minimal dose of virus, non-infective the intramuscular route, may become infective if n mixed with pertussis vaccine.

he differences observed between the effects of pertussis cine and diphtheria toxoid are in harmony with presumption that local damage to tissue is a detering factor. Since the local damage following the ction of pertussis vaccine, or combined pertussis-htheria prophylactic, is much more severe than that ally following diphtheria toxoid alone, one would ect more striking and frequent effects to follow ninistration of pertussis vaccine, even if, as is the e in Victoria, many more children are immunised inst *diphtheria*.

n considering, however, the frequency and severity of effects of pertussis vaccine, in comparison with htheria toxoid, it should be remembered that pertussis cine is usually given early in the child's life, while htheria prophylaxis is often postponed until the child four or five, and about to enter school. The average of the children in this series given pertussis vaccine, ne or in combination, was 2·4 years, and of those eiving diphtheria toxoid 5·1 years. Location of the ralysis in the injected limb may be, therefore, a enomenon more likely to occur in younger children, espective of the nature of the prophylactic agent.

One further point remains to be mentioned. A nursing ter developed typical poliomyelitis after an injection typhoid-paratyphoid vaccine into the left upper arm. en days after the injection she felt unwell and remained bed for two days. She returned to duty, but on the irteenth day developed general muscle pains and omiting. She developed considerable weakness in the jected left arm and in both legs. Another nursing sister ho received a similar inoculation at the same time ecame ill after the same interval and was diagnosed as iffering from poliomyelitis. She was not, however, ported as a case, and no further details are available.

SUMMARY

Evidence is presented that in the current epidemic of oliomyelitis in Victoria there has been a relation, in number of cases, between an injection of an immunising gent and the subsequent development of paralytic oliomyelitis.

I am indebted to the Chairman of the Health Commission f Victoria, Dr. G. E. Cole, for permission to publish this aper.

I wish to acknowledge gratefully the encouragement and uidance given me by Dr. E. V. Keogh throughout this nvestigation, and his help in the preparation of this paper. Also I wish to thank Dame Jean Macnamara (who is a constant nspiration to workers in the poliomyelitis field in Australia); Dr. H. McLorinan for his courtesy in giving me access to the patients and their records in the Infectious Diseases Hospital, Fairfield; Mr. Alwyn Mathew of the Commonwealth Serum Laboratories, Melbourne; and Dr. H. O. Lancaster of the School for Public Health and Tropical Medicine, University of Sydney, for statistical advice. Finally, I wish to thank the staff of the Health Department in Victoria who have so willingly assisted me in my investigations.

ULCERATIVE COLITIS

COURSE AND PROGNOSIS

CLINICAL MEDICINE, OXFORD

ULCERATIVE colitis varies so widely in its severity and course that the prognosis is uncertain and the assessment of new treatments is correspondingly difficult. We have investigated in a series of cases some of the factors which may influence the course of the disease and thus have prognostic significance.

MATERIAL AND METHOD

In the eleven years 1938–48 inclusive, 129 patients were treated for ulcerative colitis in the Radcliffe Infirmary. We have analysed their case-records and followed their progress. The follow-up was conducted initially by post and later at a special outpatient clinic for those still living in the area. The response to inquiry was satisfactory, 121 out of the 129 being traced.

A representative unbiased sample of patients must be studied if one is to get a clear idea of the prognosis in any disease. With a chronic and relapsing disease such as this, the total admissions to a hospital include many patients who have previously been treated in other hospitals. A disease may be more lethal in its early than in its later stages, or vice versa. Hence we have divided the patients into two groups:

New cases: 72 patients in whom ulcerative colitis had been present for less than two years before their first admission to the Radcliffe Infirmary and who had had no previous hospital treatment elsewhere.

Old cases: all other patients.

The time limit of two years was set to exclude from the new cases a few patients with the chronic continuous type of ulcerative colitis who had had diarrhœa for years before their first admission to the Radcliffe Infirmary but had not been treated in another hospital.

For the reasons given above we have concerned ourselves mainly with the 72 new cases so far as prognosis is concerned.

RESULTS

Age and Sex

Ulcerative colitis occurs chiefly in the first half of adult life. More than half of the present patients began their illness in their twenties or thirties. The disease may, however, arise at any age after infancy, though rarely before the 'teens or after the fifties. The youngest patient in this series was 5 years old and the oldest 68.

Ulcerative colitis affects both sexes, but different series have yielded very different proportions of males and females. Thus Hern (1931), Buzzard et al. (1938), and Cullinan (1938) had about twice as many women as men in their series, whereas Hardy and Bulmer (1933) and Willard et al. (1938) had roughly equal numbers of men and women. Our series contains nearly twice as many women as men, as follows:

Age-group (years)	*Male*	*Female*	*Total*
0–9	2	1	3
10–19	3	8	11
20–29	12	22	34
30–39	15	24	39
40–49	9	13	22
50–59	3	10	13
60–69	3	4	7
Totals	47	82	129

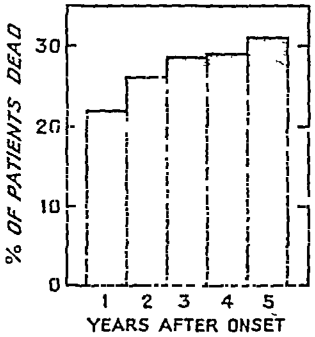
This sex difference may be partly due to the influence of war, with the removal from the civilian population of a high proportion of men of the most susceptible ages. This view gains support from the numbers of admissions in the war years and in the non-war years, as follows:

	Females	*Males*
Non-war years	29	25
War years (1940–45)	50	21

It will be seen that outside the war years there were about $2^1/_2$ times as many women as men. On the other hand, the preponderance of women extends beyond the age limits of military service, so war conditions do not entirely explain the sex difference.

Fatality

It has been the general practice to present the prognosis of ulcerative colitis in terms of the outlook for a number of patients admitted to a hospital in a stated period. This method is fallacious because such a group is heterogeneous, some of the patients having recently been affected by the disease while others may have had it for 20 years or more. Thus Hern (1931) reported a hospital mortality of 28% rising to 40% on follow-up, but his cases were a mixture of new and old patients. Hardy and Bulmer (1933) found a fatality-rate of 33% among 95 patients followed up for 1–12 years, but the duration of the disease in their cases varied from 6 weeks to 32 years. Spriggs (1934), in a study of 35 cases of ulcerative colitis followed up for 2–20 years, recorded 6 deaths from the disease (17%); but no less than 32 of his cases had had an attack before the one in which he first saw them. Willard et al. (1938) likewise gave the prognosis for a mixed group of patients, stating that "the duration of symptoms when seen by us varied from a few days to more than 17 years." The failure to separate fresh from chronic cases makes these results difficult to interpret. Prognosis should be based on the fate of patients seen in their first attack and subsequently followed up. This is the method which we have adopted.



Proportion of new patients with ulcerative colitis dead after various lengths of time.

When the fate of the new patients in the present series is considered over a number of years, the findings, also shown in the figure, are as follows:

Length of follow-up (years)	No. of patients	No. dead	Fatality-rate (%)
1	69*	15	22
2	61	16	26
3	49	14	28·5
4	45	13	29
5	39	12	31

* Of the 72 new cases, 3 were not traced in the follow-up.

After an initially high fatality-rate of 22% in the first year, the dangers associated with the disease diminish. Nevertheless, about another 10% of patients are liable to die before 5 years have elapsed. These results are only a rough estimate because we have followed up 69 patients for at least a year but only 39 patients for at least 5 years, and for periods of follow-up longer than 5 years our numbers are too small to be useful.

Of the 69 patients traced, 15 (22%) died from their first attack within a year. Of these 15 patients, 13 died in hospital, giving a fatality-rate of 19% in hospital for the first attack. This finding contrasts with the fatality-rate in hospital for relapses only, which was less than 4%. The first attack is therefore considerably more dangerous than subsequent attacks. Incidentally, this difference demonstrates the need for precision in the presentation of statistics in ulcerative colitis, and particularly the need to separate first attacks from relapses.

TABLE I—FATALITY-RATE IN HOSPITAL IN RELATION TO MODE OF ONSET (NEW CASES ONLY, IN THEIR FIRST ATTACK)

Onset	No. of patients	No. died	Fatality-rate (%)	Difference and S.E.
Acute	32	7	21·9	6·9±9·2
Gradual	40	6	15·0	

Clinical Types

A further idea of the prognosis can be obtained by classifying patients according to the type of course which the disease runs, as follows:

Group	Course of disease	No. of patients and % of total
I	*Acute fulminating:* a single attack going on to death in less than 1 yr.	15 (20·8%)
II	*Chronic intermittent:* more than one attack with at least several weeks' complete freedom between attacks	27 (37·5%)
III	*Chronic continuous:* continuous symptoms for more than 1 yr.	18 (25·0%)
IV	*Single attack:* followed by complete freedom	10 (13·9%)
V	*Unclassified:* follow-up failed	2 (2·8%)
	Total	72

This method of classification is not ideal, because it offends taxonomical canons. Thus group I is based on a fatal prognosis, groups II and III are differentiated by the type of symptom, and group IV depends on the length of follow-up. But the classification gives an idea of the proportion of different clinical types, and moreover it has been adopted by many other workers since its introduction by Hawkins (1909), so it enables results to be compared with other series.

During the period of follow-up only 2 patients in group II and 1 in group III died. Thus there seems to be little difference in lethality between the two groups. It will be seen that the chronic intermittent course seems to be rather more common than the chronic continuous. In this respect an interesting comparison can be made with our old cases. Of the 55 of these, no less than 41 were classified as chronic intermittent, compared with only 14 as chronic continuous. This is a further example of the importance of dealing with new cases only in finding out the proportion of cases which are likely to run each course. The higher proportion of chronic intermittent types among the old cases can be explained on the following grounds: (1) the bulk of group-IV patients (one attack only) eventually become examples of the chronic intermittent group; and (2) some of the patients originally belonging to the chronic continuous type undergo complete remissions and emerge finally as chronic intermittent cases.

TABLE II—RELATION OF MODE OF ONSET TO SUBSEQUENT COURSE

Mode of onset	Course of disease (group)			
	I	II	III	IV
Acute	8	13	6	5
Gradual	7	14	12	5

In tables II–IV the 2 patients in group V (unclassified) are excluded.

Further, the figures given above suggest that the single attack followed by complete freedom is fairly common. It is, in fact, far less common than appears here, and most of these patients really belong to the chronic intermittent group but have not yet had a relapse. This view is supported by comparing the proportion of group-IV patients among new cases followed up for different times. Thus, if we exclude the acute fulminating group, among 31 patients followed up for 1–5 years there were 8 patients (26%) who had had only one attack; whereas among 23 patients followed up for 6–11 years there were only 2 such patients (9%). This last figure shows how small is the chance of avoiding a second attack over a period of 10 years or so.

Mode of Onset

Ulcerative colitis may first manifest itself acutely with bloody diarrhœa or it may begin gradually with mild diarrhœa or streaking of the stools with blood. An obvious question is whether the type of onset has any bearing on the subsequent course. Table I shows that there is no significant difference in fatality-rate between patients with acute and with gradual onsets.

The comparison is extended in table II, which shows the distribution of the four clinical types in relation to the mode of onset. The two sets of figures are closely similar, and the differences between them are not statistically significant ($\chi^2=1{\cdot}6$; 3 degrees of freedom; $P>0{\cdot}5$). We may conclude that the mode of onset has little bearing on the subsequent course of the disease.

Sex and Age

Published reports contain conflicting statements about the effect of sex and age on the prognosis of ulcerative colitis. Table III sets out the data from the present series.

TABLE III—INFLUENCE OF SEX AND AGE ON COURSE OF ULCERATIVE COLITIS (NEW PATIENTS ONLY)

Age-group (yr.)	Course of disease (group)							
	Men (26)				Women (44)			
	I	II	III	IV	I	II	III	IV
10–	1	1	..	..	1	2	1	..
20–	3	2	..	..	2	6	3	..
30–	1	3	2	2	2	5	4	5
40–	1	3	2	..	1	3	1	..
50–	..	..	1	1	2	1	2	1
60–	..	..	2	1	1	1	..	..
All ages	6	9	7	4	9	18	11	6

From the figures for all-ages it will be seen that sex seems to have little influence on the subsequent course of the disease. Similarly, if the cases of each sex are combined, as in table IV, age likewise appears to have little influence on prognosis. At first sight the proportion of cases which run a rapidly fatal course seems to be unduly high in patients under 30, but this difference is not statistically significant.

In table III the men and women are differently distributed. Among the women there is no obvious difference between the various age-groups. Of the men, 4 out of 7 under 30 died in less than a year, compared with only 2 out of 19 over 30. But statistical analysis shows that this difference might occur fairly often by chance. (Dr. Ian Sutherland, of the Institute of Social Medicine, Oxford, kindly checked this point.)

Degree of Activity

In addition to its lethal qualities, ulcerative colitis is important as a source of chronic ill health. We have therefore tried to assess its effect on the patient's mode of life. From our follow-up data we have classified patients in the following manner, which, though crude, gives a rough picture of their progress (we have omitted patients who died during the course of follow-up, because these have been previously discussed):

A, living a normal or near-normal life, even though they may be subject to diarrhœa, either continuously or in attacks.

TABLE IV—INFLUENCE OF AGE ON COURSE OF ULCERATIVE COLITIS

Age-group (yr.)	Course of disease (group)				Total
	I	II	III	IV	
Under 40 ..	10	19	10	7	46
40 and over ..	5	8	8	3	24
Under 30 ..	7	11	4	0	22
30 and over ..	8	16	14	10	48

B, living restricted lives, often interrupted by hospital admissions.

C, chronic invalids.

TABLE V—DEGREE OF ACTIVITY (NEW CASES ONLY)

Course of disease (group)	Degree of activity			Total
	A (normal)	B (restricted)	C (invalid)	
II	10 (*40%*)	14 (*56%*)	1 (*4%*)	25
III	6 (*37%*)	8 (*50%*)	2 (*12 5%*)	16
Total	16 (*39%*)	22 (*53%*)	3 (*7%*)	41

Table V shows how the new cases were distributed among these three categories.

It will be seen that about 40% of patients are living normal or near-normal lives, about 50% are moderately incapacitated, and *only* a small proportion are totally incapacitated. A striking feature of table V is the close similarity between the chronic intermittent and chronic continuous clinical types of the disease (groups II and III) in their influence on the patient's mode of life.

Treatment

It is not our intention to deal with treatment except in relation to one or two isolated aspects. Throughout the period under review there were no sharp changes in the main lines of medical treatment, which consisted of rest in bed; high-calorie, high-protein, low-residue diets; vitamin supplements; blood-transfusion; control of salt and fluid balance; and various rectal instillations. However, during this period penicillin and the non-absorbable sulphonamides were introduced, and it is of interest to assess the effects of these therapies.

Table VI compares the results of treating patients with and without penicillin and/or sulphonamides. The close similarity between the two treatment groups is evident. The comparison is made on the response to treatment at the time of discharge from hospital and *not* on the apparent effects of these therapies over very brief periods of time. We are satisfied that the two groups did not differ materially as regards other forms of treatment. For reasons which we have already emphasised we have separated patients in their first attack from those admitted in relapse. Table VI is concerned only with new patients in their first attacks only. For patients admitted in relapses similar results were obtained.

TABLE VI—EFFECT OF TREATMENT (NEW PATIENTS IN FIRST ATTACK)

Treatment	Results on discharge from hospital				Total
	Symptom-free	Fair response	Poor response	Dead	
Penicillin and/or sulphonamides	7 (*30 5%*)	8 (*34 6%*)	4 (*17 5%*)	4 (*17 5%*)	23
Neither	18 (*37 5%*)	15 (*31 3%*)	5 (*10 4%*)	10 (*20 8%*)	48

Thus, so far as we can judge, penicillin and sulphonamides have no effect on the course of ulcerative colitis. This does not mean that they are useless—they are almost certainly valuable in preventing and treating pyogenic complications and when used prophylactically before and after operation—but they do not seem to influence appreciably the long-term course of the illness. Similar conclusions have been drawn by Kiefer (1948) and Block and Pollard (1948).

Though we shall not discuss in detail the value of surgery, it should be mentioned that emergency ileostomies done in an attempt to avert death when medical measures seem to be failing do not appear to be justified by this series. Of 10 patients so treated 6 died shortly afterwards. On the other hand, ileostomy or colostomy done as an elective operation in 6 patients caused no deaths. In these patients the operation was done because of some definite complication: stricture in 3 patients and fæcal fistulæ in 3 patients. This is in line with the recent conclusion of Cattell (1948), who found that two-thirds of the fatal cases following ileostomy occur when the operation is done as an emergency. He states that over a 20-year period the mortality with surgical intervention was 22%, but during the last 2 years it had dropped to 4%. One of the causes of his improved results has been the avoidance of emergency operations whenever possible.

DISCUSSION

In spite of the many recent advances in medicine, ulcerative colitis remains dangerous and disabling. In an attempt to estimate as accurately as possible how dangerous and how disabling it is, we have analysed its course in a group of patients admitted to a general hospital in the first attack and followed for 1–11 years. We believe that the results so obtained are more accurate than figures drawn from a heterogeneous group of patients admitted to hospital in all stages of the disease. The failure of workers in this field to distinguish between new and old cases vitiates most previous estimates of prognosis.

The first year of ulcerative colitis is the time when death is most likely to take place, and it is this phase which must be better treated if the present high fatality-rate is to be reduced. Surgery seems to offer no solution at this stage, and our findings, together with those of others, have led us to the belief that emergency ileostomies should not be done. Better results seem to have been obtained by vigorous medical therapy, particularly by replacing electrolytes, blood, and protein by intravenous infusions. Chemotherapy and treatment with antibiotics have been disappointing, and some more specific remedy is probably needed before any further advance can be made.

If the first year of ulcerative colitis is survived, the chances of death diminish considerably. Nevertheless half the survivors lead restricted lives, and in this respect it seems to make little difference to the patient whether the disease pursues a continuous or an intermittent course, and the chances of avoiding further relapses are remote. We have shown that 90% of our new patients had relapsed when followed up for 6–11 years. It is worth adding that among the chronic intermittent cases of the whole series, 20% had periods of freedom between attacks lasting 5 years or more. These findings indicate that claims to have effected a cure of ulcerative colitis, especially as the result of some specific treatment, must be accepted with reserve.

In view of the unsatisfactory state of medical treatment of the chronic form of ulcerative colitis and the high rate of relapse, it is worth considering the possible place of surgery. In our series elective ileostomies and colostomies were done for complications only, but in view of the fact that 50% of the patients are leading restricted lives we believe that surgical treatment might be more often advised in patients who have had ulcerative colitis for several years. However, we have no figures of our own to support this belief, and in each case the balance must be carefully weighed between the inconveniences of the disease and the ileostomy life.

SUMMARY

In the eleven years 1938–48 there were 129 patients with ulcerative colitis admitted to the Radcliffe Infirmary. Of these, 72 were new cases—i.e., of recent onset and not previously treated in another hospital.

Of the 72 new cases 22% died within a year of their onset. Thereafter ulcerative colitis seems to be less lethal, but about a third of these patients are dead at the end of five years.

The risk of recurrence is high. Few patients avoid a second attack over the course of a number of years.

Age, sex, and the mode of onset have little bearing on prognosis.

Half the patients live restricted lives, and a small proportion are totally incapacitated. The effect of ulcerative colitis on the patient's activity does not seem to depend greatly on whether it runs a continuous or an intermittent course.

Penicillin and sulphonamides have not materially affected the course of ulcerative colitis.

Emergency ileostomies do not seem to be justified.

We wish to thank the physicians of the Radcliffe Infirmary for permission to study their patients; Prof. L. J. Witts for helpful criticism; and the staff of the records department for their assistance.

CONGENITAL ŒSOPHAGEAL ATRESIA WITH TRACHEO-ŒSOPHAGEAL FISTULA

A REPORT OF 5 CASES AND A PLEA FOR EARLY DIAGNOSIS

BRIAN DONNELLY
M.R.C.S., D.M.R.
ASSISTANT RADIOLOGIST, ADDENBROOKE'S HOSPITAL, CAMBRIDGE

THE prognosis in congenital atresia of the œsophagus with tracheo-œsophageal fistula is now exceedingly bad. Though Grey Turner (1944) estimates that 1 baby in every 2650 is born with atresia of the œsophagus there are probably not more than two or three cases surviving in this country. Most of these infants have an advanced aspiration pneumonia by the time they reach the surgeon. Grey Turner (1949) says:

> "Even now I do not think a sufficient number of these cases come before the surgeon at the proper time and I believe that we still require to carry on propaganda among obstetricians, maternity nurses, midwives and even pædiatricians directed to their early recognition."

If more cases were recognised earlier and operated on before the onset of pneumonia, some at least would be saved. My five fatal cases are reported in the hope that they will help others to make an early diagnosis.

Leven (1936) states that the condition was first described by Gibson in 1696; and he mentions two cases, one of which survived for 98 days after operation. Strong and Cummins (1934) say that the abnormality was mentioned by Morell Mackenzie in 1884, and they describe one case which died after jejunostomy.

In America, the condition has been reported more frequently since 1930. Reitter (1933) recorded one case; and Gage and Ochsner (1936) reported two cases, both of which died after gastrostomy and ligation of the tracheo-œsophageal fistula. The case described by Kassebohm and Schrieber (1936) was diagnosed radiologically after the administration of barium sulphate by mouth. Rosenthal (1937), in an account of three cases, recommended giving the barium through a catheter, to prevent regurgitation and aspiration. O'Hare (1937), who mentioned that 281 cases had been reported by 1933, described one case which also had an imperforate anus; the atresia of the œsophagus was diagnosed by endoscopy and by noting the obstruction o the passage of a stomach-tube. A further case is described by Gamble (1938). Congenital œsophageal atresia is described in many textbooks, notably by Abel (1929) and Illingworth and Dick (1938).

The embryological classification of Vogt (1929) has been accepted by most writers:

Type 1.—Complete absence of the œsophagus.

Type 2.—Atresia of the œsophagus with both the upper and lower segments ending blindly.

Type 3.—(*a*) Atresia of the œsophagus with a fistula between the upper œsophageal segment and the trachea.

(*b*) Atresia of the œsophagus with a fistula between the lower œsophageal segment and the trachea.

(*c*) Atresia of the œsophagus with a fistula between the trachea and both segments of the œsophagus.

In this country, Bull (1938) reported a case in which the upper blind œsophageal pouch was revealed by X-ray examination after a barium-in-milk feed and the tracheo-œsophageal fistula was demonstrated post mortem by further X-ray examination after the injection of iodised oil into the trachea. This infant also had a hemivertebra in the dorsal region, and an atrophic left kidney and left genital tract. Other cases have been reported by Addey (1940), by Calvert (1943), and by Ealing (1940), who suggested that œsophagoscopy and bronchoscopy might be the best methods of investigation, the administration of barium by mouth being contraindicated because of the danger of aspiration pneumonia. Grey Turner (1944) described the condition very fully and mentioned a case which died 17 hours after operation.

OPERATION

From 1940 onwards, much progress was made towards devising an effective operation for the condition. According to White and Birdsong (1946), Leven, Ladd, and Haight each had cases surviving from operations performed as early as 1940–41.

Haight (1944) described a one-stage operation with primary anastomosis of the two divisions of the œsophagus and ligation of the tracheo-œsophageal fistula. In 1944 about 30 cases survived this operation.

Ladd and Swenson (1947) and Leven and Lannin (1945) favoured the multiple-stage operation described by Leven (1941). First the tracheo-œsophageal fistula is ligated and a gastrostomy performed; at a second operation the upper œsophageal segment is brought to the surface; and then later an anterior œsophagus is constructed.

Lam (1946) reported some successes with primary anastomosis, and this type of operation was chosen by Franklin (1948), who seems to have been the first to publish details of a successfully treated case in this country.

DIAGNOSIS AND MANAGEMENT

Very early diagnosis is essential if a very young infant is to survive any of these formidable procedures. Signs of dehydration are usually evident soon after birth. Regurgitation and aspiration of feeds leads rapidly to bronchopneumonia. The diagnosis of congenital œsophageal atresia should be considered if regurgitation, combined with attacks of cyanosis from the first feed onwards, is associated with excessive mucus and saliva in the mouth and pharynx. Attempts at feeding should be stopped and pharyngeal suction instituted forthwith. The diagnosis can be confirmed only by X-ray examination, which should be carried out as soon as possible; meanwhile, the child should be nursed in the prone position to ensure effective drainage of saliva from the mouth. Fluids should be given intravenously and a course of penicillin begun.

X-ray Examination

Intermittent pharyngeal suction, using a rubber pipette, is continued until the mouth and pharynx are reasonably dry. An œsophageal tube is then passed until obstruction is met with. No attempt should be made to push the tube farther in, since it may coil up and give the impression that it has passed into the stomach. The infant is then held upright, to avoid spilling over into the larynx, and 2 ml. of iodised oil is injected down the tube. X-ray films are exposed in the anteroposterior and lateral positions to include the whole of the chest and abdomen. The oil is then immediately withdrawn and pharyngeal suction recommenced.

In addition to confirming the diagnosis, X-ray examination reveals the condition of the lungs. If collapse or consolidation is noted, and if this is chiefly confined to one side, the child's position is adjusted so that postural drainage will be as efficient as possible. If an infant with œsophageal atresia is found to have air in the stomach and bowel the presence of a tracheo-œsophageal fistula may be assumed, though the absence of gas shadows in the abdomen does not prove that there is no fistula, since the opening may be valvular.

The length of the gap between the two œsophageal segments should be estimated. This can be done by direct measurement if air can be seen in the lower œsophageal segment on the lateral film. In the five cases reported here no air could be seen in the lower part of the œsophagus, so an indirect method of estimating the gap was devised. The distance between the lower limit of the upper œsophageal segment and the bifurcation of the trachea was measured, and this gave the surgeon an accurate enough indication of the difficulty to be encountered in joining the two œsophageal segments. In all five cases, the lower segment of the œsophagus communicated with the trachea within 1 cm. of the bifurcation.

Finally, the presence of other congenital abnormalities may be detected.

CASE-RECORDS

Case 1.—A girl, aged 5 days, was admitted on June 17, 1947. Weight at birth 6 lb.; on admission 5 lb. 11 oz. Instrumental breech delivery. On the 3rd day after birth it had been noticed that the breast-feeds were being regurgitated. The infant had been taken off the breast but had continued to vomit glucose-water feeds. The vomit had contained no bile but an excessive amount of mucus. The bowels had been opened normally each day.

The child looked wasted and dehydrated. No abnormal physical signs were detected apart from coarse râles over the whole of both lungs. The infant could keep down 2–3 teaspoonfuls of a feed for 20–30 seconds, but then the whole feed would be regurgitated. All mouth-feeding was stopped and fluids were given intravenously. A provisional diagnosis of tracheo-œsophageal fistula was made.

On June 19 X-ray examination of the chest revealed consolidation in the right upper zone. A further examination next day showed œsophageal atresia. Some of the iodised oil spilled over into the trachea and was seen to pass into the stomach through a tracheo-œsophageal fistula. The child died on June 22.

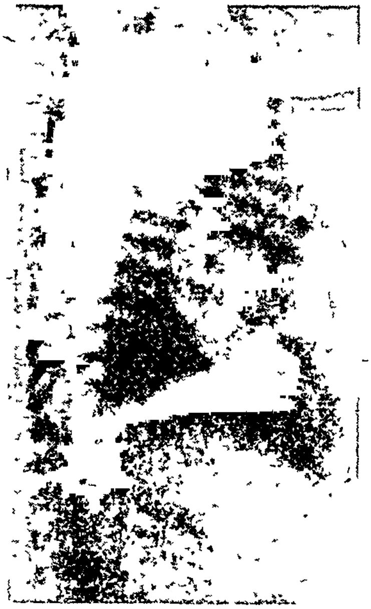
Necropsy.—The upper portion of the œsophagus ended blindly, 3·8 cm. below the cricoid cartilage, in a pouch 1·2 cm. in diameter. The lower portion of the œsophagus communicated with the trachea 0·5 cm. above its bifurcation through an opening 0·25 cm. in diameter externally. Below this point the lumen of the œsophagus appeared normal. The ductus arteriosus was patent but contained a recent thrombus with commencing organisation. Microscopy of the lungs showed extensive severe bronchopneumonia. No other abnormality was detected.

Case 2.—A girl, aged 2 days, was admitted on Feb. 19, 1948. Weight at birth and on admission 5 lb. 2 oz. Instrumental delivery. The child had been unable to swallow breast-feeds and appeared to be choked with mucus; attempts at feeding had been followed by cyanosis. The bowel action had been normal.

The skin was dry, wrinkled, and jaundiced. The 4th and 5th toes of both feet were webbed, though X-ray examination later showed that the bones were normal. No other abnormal physical signs were detected.

X-ray examination on the day of admission showed that the œsophagus ended blindly, opposite the body of the 3rd thoracic vertebra, in a large pouch which moved on respiration and appeared to be causing considerable forward displacement and compression of the trachea (see figure): presence of gas in the stomach confirmed the diagnosis of a tracheo-œsophageal fistula. The gap between the œsophageal segments was estimated to be about 2 cm. The lungs seemed clear and no other congenital abnormality was seen.

On the same day (Feb 19) the tracheo-œsophageal fistula was closed. At a second operation, on Feb. 21, a gastrostomy was done, followed by œsophagostomy of the upper œsophageal segment. On the 22nd hydration was fair but the child's general condition was deteriorating. She died on the 23rd.



X-ray appearances in œsophageal atresia after introduction of iodised oil.

Necropsy.—The œsophagus ended blindly 5 cm. below the epiglottis, the lower end having been brought forward and sutured to the skin on the left side of the neck; the œsophageal pouch was 2·8 cm. in circumference. The lower œsophageal segment, which measured 2·3 cm. in circumference, opened into the trachea at its bifurcation; the opening was valvular and it was more difficult to pass a probe from the tracheal side. A gastrostomy was present. The left lung was collapsed and the right showed severe bronchopneumonia.

Case 3.—A girl, aged 5 days, was admitted on April 8, 1948. Weight at birth 6 lb. 8 oz. From birth the child had regurgitated all feeds and had an excess of mucus in the mouth and pharynx. Attacks of cyanosis had followed attempted feeding.

The child was cyanosed and there were signs of partial atelectasis of both lungs. No other abnormal physical signs were detected.

X-ray examination on the day of admission showed that the œsophagus ended blindly in a pouch opposite the upper border of the sternum. The stomach contained a moderate amount of gas, confirming the presence of a tracheo-œsophageal fistula. The lungs showed partial consolidation with some collapse. No other abnormality was detected.

At operation on the day of admission the tracheo-œsophageal fistula was ligated and the two œsophageal segments anastomosed. Shortly afterwards the child's general condition deteriorated and she died next day.

Necropsy.—The primary anastomosis of the œsophageal segments with ligation of the tracheo-œsophageal fistula, which was at the lower end of the trachea, had been successful. The ductus arteriosus was patent but contracted. Microscopy of the lungs showed severe bronchopneumonia with partial collapse. No other congenital abnormality was found.

Case 4.—A girl, aged 2 days, was admitted on April 19, 1948. Weight at birth 6 lb. 8 oz. The mother's labour had been protracted, and there had been much difficulty in resuscitating the infant. Excess of mucus had been noticed in the mouth and pharynx; she had not sucked well and appeared to be cyanosed.

When examined in hospital the infant had bloodstained mucus welling out of her mouth and moist sounds at the base of both lungs. She had passed very dark meconium. The provisional diagnosis was inhalation pneumonia, possibly associated with congenital œsophageal atresia.

X-ray examination on April 20 showed that the œsophagus ended blindly opposite the anterior margin of the body of the 3rd thoracic vertebra. The stomach contained only a little air, suggesting that the tracheo-œsophageal fistula might be small. The upper zones of both lungs were consolidated.

The child was too ill for operation, and she died on April 21.

Necropsy.—The œsophagus ended blindly in a large pouch, 5·0 cm. below the epiglottis; the diameter of this part of the œsophagus was 1·4 cm. The lower part of the œsophagus was continuous with the upper segment, but attempts to pass a probe from above downwards and from below upwards were unsuccessful; the lower part extended upwards on the anterior surface of the lower end of the upper segment and opened into the trachea 0·7 cm. above its bifurcation. The opening of the fistula was 0·2 cm. in diameter. A small Meckel's diverticulum was found. The right hypogastric artery was absent and the right common iliac artery was only 0·3 cm. in circumference. The left common iliac artery seemed large and measured 1·1 cm. in circumference. Both lungs showed extensive bronchopneumonia. No further congenital abnormality was detected.

Case 5.—A boy, aged 5 days, was admitted on Sept. 9, 1948. Weight at birth 6 lb. 8 oz. Normal delivery. From birth the child had had an excess of mucus in his mouth, requiring frequent aspiration; at each feed he had choked and become cyanosed, but feeding had been persisted with until the day of admission.

The child's general condition seemed fair and there was no dehydration. No abnormal physical signs were found in the lungs. Administration of penicillin was begun.

X-ray examination on the day of admission showed that the œsophagus ended blindly about 2·5 cm. above the tracheal bifurcation. A moderate quantity of gas was present in the bowel. The lungs appeared clear and the cardiac outline normal.

At operation on the same day the tracheo-œsophageal fistula was ligated and the two segments of the œsophagus anastomosed. The child died 3 hours later.

Necropsy.—The primary anastomosis of the œsophageal segments with ligation of the tracheo-œsophageal fistula had been successful. The upper segment of the œsophagus appeared to have about twice the diameter of the lower. The ligated tracheo-œsophageal fistula opened into the trachea 0·8 cm. above its bifurcation. A pneumothorax was present on the right side. The ductus arteriosus was patent but contained thrombus. On microscopy, the lungs showed extreme congestion but no evidence of bronchopneumonia. No other congenital abnormality was detected.

DISCUSSION

In managing cases of congenital œsophageal atresia the presence of other associated congenital abnormalities is very important. If other conditions incompatible with a full and useful life were often found in addition to œsophageal atresia, it would be a waste of time and energy to attempt to treat these infants, but this series shows once again that in many infants atresia of the œsophagus with a tracheo-œsophageal fistula is the only significant abnormality present. Ladd and Swenson (1947) found that of their 82 cases only 18 had serious additional abnormalities, and these were chiefly in the heart.

There may, however, be many undiagnosed cases of œsophageal atresia in which the infants die immediately after birth from associated congenital abnormalities which are incompatible with life. This may be why Vogt's (1929) type 3b of congenital atresia is the most common variety reported; for in most of the other types the child is drowned at the first feed. Holt et al. (1946) agreed that type 3b is the commonest; and all the five cases in the present series fall into this group. The fact remains that the lives of some of these infants can be saved if the atresia is diagnosed sufficiently early. Thus Haight (1944) showed that reconstruction of the œsophagus by primary anastomosis was possible in 16 of the 24 cases he operated on.

In case 5 of the present series necropsy showed no evidence of pneumonia, although attempts to feed the child had been continued for 5 days. This child probably escaped pneumonia because of the administration of penicillin, the frequent pharyngeal aspirations, and the presence of a well-developed pharyngeal reflex. In most cases treatment must be instituted in the first day or two of life if pneumonia is to be avoided and surgery is to have any chance of success.

I wish to thank Dr. L. B. Cole, Mr. B. M. Truscott, Dr. D. M. T. Gairdner, and Dr. Janet Roscoe for permission to publish details of their cases; Dr. A. M. Barrett for the necropsy reports; and Dr. F. R. Berridge for his helpful advice and criticism.

CARBON DIOXIDE LEVELS IN BABIES' OXYGEN BOXES

ALISTAIR MACKENZIE
M.B. Durh., D.A.
FIRST ASSISTANT, DEPARTMENT OF ANÆSTHETICS, DURHAM UNIVERSITY

VERY little information has been published on the carbon dioxide levels, oxygen tensions, temperatures, and relative humidities in the air breathed by babies in oxygen boxes. The following findings may therefore be of value.

METHOD

The boxes used for the trials were of the usual rectangular bottomless form and measured 23 × 14 × 13 in. deep; they were made of metal with transparent plastic panels in the sides and top. The tests were made in clinical conditions at the Princess Mary Maternity Hospital, Newcastle upon Tyne, with the box either resting directly on the mattress or raised from it so as to leave a $^3/_4$ in. ventilation gap at the foot. The occupants were healthy babies weighing 5–8 lb.

Oxygen estimations, accurate only to ± $2^1/_2$%, were made by drawing gas samples from the head end of the tent through narrow-bore rubber tubing into a Riseman-Lesnick oxygen analyser. Samples for carbon dioxide estimation were similarly drawn into mercury-filled Hempel pipettes and analysed by Van Slyke's manometric method. Relative humidity was estimated with a miniature Assman type psychrometer.

The oxygen flow was accurately measured and the gas humidified at room-temperature on its way to the box. The makers' suggested flow-rate was 5 litres per minute for 5 minutes and thereafter $1^1/_2$ litres per minute; this rate was used as a basis for the tests.

RESULTS

At the originally recommended rate of oxygen flow, oxygen concentrations in the box may reach 60%, but carbon dioxide concentrations were consistently 1% or more (see table).

CONDITIONS IN OXYGEN BOXES

Test no.	Carbon dioxide (%)		Oxygen (%)		Temperature (°C)		Relative humidity	
	After $^1/_2$ hr.	After 1 hr.	After $^1/_2$ hr.	After 1 hr.	Room after 1 hr.	Box after 1 hr.	Room after 1 hr.	Box after 1 hr.
Oxygen 5 litres/min. for 5 min.; then $1^1/_2$ litres/min. (no ventilation gap)								
1	0·92	1·31	..	..	18·5	20·5	24	59
2	1·00	1·43	..	..	..	..	..	..
3	0·49	1·03	60	65	..	..	..	..
Oxygen 6 litres/min.; then 3 litres/min. (no ventilation gap)								
4	0·27	0·74	59	72	..	..	..	..
5	0·59	0·57	73	81	19	24	42	49
6	0·79	1·26	..	..	23	31	37	87
Oxygen 6 litres/min. for 5 min.; then 3 litres/min. ($^3/_4$ in. ventilation gap)								
7	0·64	0·52	52	54	22·5	20·5	34	59
8	0·49	0·65	51	52	21·5	24	39	66
9	0·28	0·27	50	50	..	..	..	..
Oxygen 5 litres/min. for 5 min.; then 3 litres/min. ($^3/_4$ in. ventilation gap)								
10	0·53	0·45	39	39	..	..	..	..

An increase in the maintained rate of flow to 3 litres per minute produced carbon dioxide concentrations below 1%, except in the case of an 8 lb. baby (test no. 6) crying lustily, when the relative humidity in the box also became high. With this rate of flow, the oxygen concentrations were usually higher than with the slower rate (see table).

When a ventilation gap was created at the foot of the box, carbon dioxide tensions tended to be yet lower, but even the higher rate of oxygen flow yielded only about 50% oxygen concentration (see table). Using the ventilation gap with the originally recommended rate of flow gave oxygen concentrations of only 39%.

CONCLUSION

The conditions desired inside the box must be determined by the clinician for each individual case. In my view an oxygen flow of 6 litres per minute for 5 minutes, followed by 3 litres per minute, with the box placed directly on the mattress, will generally be needed.

LEAKAGE OF AIR FROM PNEUMOPERITONEUM INTO PLEURAL CAVITY

E. W. STREET
M.R.C.S.
SENIOR ASSISTANT MEDICAL OFFICER, LENHAM SANATORIUM, KENT

IN view of the widespread use of artificial pneumoperitoneum in the treatment of pulmonary tuberculosis, the following case is of interest because of the unusual complication.

A man, aged 24, was admitted to Lenham Sanatorium on Oct. 25, 1948, with bilateral pulmonary tuberculosis, which had first been diagnosed in January, 1948. A pneumoperitoneum (P.P.) was induced on Feb. 3, 1949, and maintained with weekly refills of about 800 c.cm. of air. Satisfactory rise of both domes of the diaphragm was obtained, but this treatment was regarded only as a preliminary to bilateral artificial pneumothorax (A.P.), which was considered necessary to control the tuberculosis. Hence on April 28 a right A.P. was induced, and this was followed by thoracoscopy and a satisfactory section of adhesions on June 8. The P.P. was still being maintained on June 20, when a routine radiogram showed that the right A.P. was still quite shallow.

On June 29, the patient received his weekly refills—A.P. 500 c.cm.; P.P. 600 c.cm.—and later the same day he consumed an immoderate quantity of fresh fruit. This was thought to be the cause of a violent attack of vomiting which followed soon afterwards, and which was accompanied by sudden dyspnœa. This distressed condition did not last more than an hour, and when the patient was seen next morning he seemed to have fully recovered and was no longer dyspnœic. Physical examination did not reveal any unexpected signs.

Radioscopy a week later, before his next refills, showed that the P.P. had completely disappeared, the A.P. was much larger, and the right lung had almost completely collapsed.

The only explanation for these findings is that air had gone from the peritoneal cavity to the right pleural cavity. This was confirmed by the intrapleural pressures, which were higher than the final readings of the week before.

DISCUSSION

Though the P.P. in this case was not a particularly large one, it must have contained at least 1500 c.cm. of air at the time of the accident, which happened only a few hours after a refill. It is therefore surprising that the constitutional upset was not more profound. The patient was fortunate in that the leakage occurred on the right side, so that the opening in the diaphragm was presumably sealed by the liver, thus averting a diaphragmatic hernia.

Banyai[1] and Sita Lumsden[2] have each reported a similar leakage; Mellies[3] reported a case of rupture of a tuberculous lesion of the diaphragm during P.P. treatment; and Smith[4] reported a case due to defects in the diaphragm. Banyai[5] reported two cases in which the leakage was in the opposite direction—from pleural cavity to peritoneal cavity—and he suggested that the air passed along mediastinal structures traversing the diaphragm. When an A.P. is not already present the diagnosis from a spontaneous pneumothorax would be difficult.

The intraperitoneal pressure must obviously be a factor in the causation of such an injury, but in the present case the resting pressure was not remarkable— + 10 cm. of water. During an attack of vomiting no doubt this pressure would be very greatly increased.

Laird[6] describes air-containing vesicles projecting from the upper surface of the diaphragm which may sometimes be seen on thoracoscopy in cases with a P.P., and postulates the rupture of such a vesicle as the cause of a pneumothorax during P.P. treatment. In patients with a P.P. it is also not unusual for the outline of the diaphragm to present on radiography a lobulated appearance which may be due to Laird's "vesicles." In the present case the right dome of the diaphragm showed this feature.

Medical Societies

EDINBURGH OBSTETRICAL SOCIETY

Pelvic Tuberculosis in the Female

AT a meeting of the society on March 8, with Dr. E. CHALMERS FAHMY, the president, in the chair, pelvic tuberculosis in the female was discussed.

Prof. CHARLES CAMERON compared genital tuberculosis in the male and in the female. In the male the incidence was 5% of all tuberculous lesions; and in 60% of cases the disease at this site was associated with renal lesions. In the female the incidence of genital tuberculosis was higher, but it was infrequently associated with renal lesions. Because localising symptoms were commonly absent, and because many of these cases were treated surgically in gynæcological wards, genital tuberculosis was seldom seen or diagnosed by sanatorium workers.

Clinically, the condition presented as an isolated tuberculous phenomenon, although there might be a history of pleurisy or of some other transient tuberculous condition. The mode of infection was usually via the blood-stream, although direct involvement from widespread tuberculosis of the peritoneal cavity was possible. Routine endometrial biopsy in cases of sterility brought to light more cases of tuberculous endometritis; and this was almost always associated with tubal involvement. Diagnosis was by no means easy, but it might be aided by culture of the menstrual blood. Genital tuberculosis was a problem to be faced jointly by specialists in tuberculosis and in gynæcology, and there was still much to learn about its diagnosis, pathogenesis, significance, and treatment.

Dr. W. D. A. CALLAM analysed 67 consecutive cases of pelvic tuberculosis. This, he said, was a disease of the child-bearing years. The presenting symptoms were pelvic pain and vaginal bleeding. Amenorrhœa was uncommon, but the incidence of infertility in the series was 84%. In 40% of the patients there was evidence of tuberculosis elsewhere, especially in abdominal organs and lymph-glands and lungs. The common sites of genital involvement were the tubes, uterus, and ovaries, in that order, but in 2 cases the cervix was involved. With regard to treatment, in 24 (36%) of the cases this was conservative, consisting in advice on diet and general hygiene; and, in the absence of available beds in sanatoria, this had to be carried out in the patients' own homes. Of 43 patients treated surgically, with an operative mortality of 7%, 23 underwent hysterectomy with bilateral salpingo-oöphorectomy, while the remainder had less extensive operations. Follow-up revealed that a further 12% of the patients had died from a tuberculous lesion, while 80% of the survivors claimed good health.

Amongst the conclusions to be drawn from study of this series was the apparently low incidence of genital tuberculosis and the infrequent evidence of associated tuberculosis elsewhere in the body. Without laparotomy, pelvic tuberculosis was difficult to diagnose, but perhaps the newer cultural methods would prove helpful. Therapeutically, the best results seemed to have followed radical surgery. Controlled clinical investigation of the effects of streptomycin and *p*-aminosalicylic acid were urgently required; these drugs might provide the solution to the problem of managing this dread disease.

HUNTERIAN SOCIETY

Diagnosis and Treatment of Phthisis

AT a dinner meeting of the society on March 20, with Dr. W. THOMSON BROWN in the chair, Dr. GEOFFREY MARSHALL and Mr. HOLMES SELLORS opened a discussion on modern trends in the diagnosis and treatment of pulmonary tuberculosis.

Dr. MARSHALL, illustrating the present position in diagnosis, showed that single radiographs could not be depended on to exclude the disease. A repetition and the closest inspection were required before a certain opinion could be given. Similarly a negative report on the examination of a smear of the sputum for tubercle bacilli was quite inadequate; in any doubtful case a culture was an absolute necessity, since this test is far more delicate than a whole series of ordinary smear investigations. Turning to treatment, he showed how important were ordinary routine measures, but how they must be supported by active treatment such as collapse therapy in its various forms. Of the chemotherapeutic agents and antibiotics, streptomycin was of undoubted value in the early stages, its main disadvantage being the tendency of the tubercle bacillus to become resistant, but the trials conducted under the auspices of the Medical Research Council had confirmed that if *p*-aminosalicylic acid (P.A.S.) was given along with streptomycin this tendency was greatly reduced. Further experiments in dosage and with other agents were being considered, but there was little doubt that the use of these substances had been one of the major advances of recent times.

Mr. HOLMES SELLORS began by comparing the rôle of the thoracic surgeon in tuberculosis to that of a demolition squad rather than a fire-brigade. The surgeon's problem was essentially that of dealing with tuberculous cavities and fibrotic contractures, and in this he had several methods of approach. Collapse therapy was the best known, but excision, in the form of lobectomy or pneumonectomy, had a considerable part to play, though its final place in treatment had not yet been determined. A further method of surgical treatment was the drainage of cavities, using either a Monaldi drainage or a deliberate cavernostomy. In this latter procedure a flap of skin and muscle was drawn into the cavity and its healing observed from below upwards. There was still a considerable amount of dispute about the relative advantages of thoracoplasty and extrapleural operations, the latter having gained in favour in the last year or so. Mr. Sellors preferred thoracoplasty as the routine and standard method of collapse, since it was both permanent and selective, and in well-chosen cases gave most satisfactory results. When extrapleural operations were done there were the questions of what was to happen if the artificial extrapleural pneumothorax was given up, and what would happen in the long run to foreign bodies used to fill the space made at the operation.

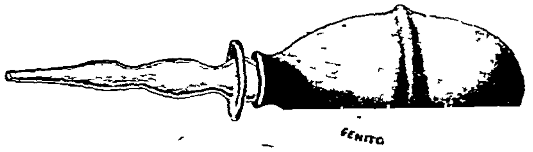
Dr. KENNETH PERRY spoke of the value of fluorescent methods of recognition of the tubercle bacilli and of some of the chemotherapeutic agents which had not yet been finally asessed.

Dr. GEORGE DAY briefly reviewed the present tendency of tuberculosis treatment, and stressed the need for realising that in the long run it was the resistance of the patient's body and tissues that determined the outcome.

New Inventions

A URETHRAL SYRINGE

THE Canny Ryall urethral syringe is ideal for injecting a local anæsthetic into the urethra but is unsuitable for irrigation of a catheter because the nozzle does not give an airtight fit. It has been modified as in the figure to form a syringe which is suitable either for local (surface) anæsthesia, or for aspiration or irrigation of an indwelling catheter. The external diameter at the tip is $^3/_{16}$ in. and at the first expansion $^3/_8$ in. The internal diameter at the tip should be at least $^3/_{32}$ in. The projecting collar at the proximal end prevents the rubber bulb from slipping down the glass nozzle at the first sign of wear. A syringe of 2-oz. capacity has been found of most value in general use but larger or smaller sizes could be made.



After any form of closed prostatectomy this syringe can be used for aspiration of the catheter in case of blockage; it is sufficiently cheap for a separate syringe to be kept for each patient, and it can be sterilised by boiling.

The syringe has been made for me by the Genito-Urinary Mfg. Co. Ltd., of 28a, Devonshire Street, London, W.1. E. W. RICHES, M.C., F.R.C.S.

Reviews of Books

Handbook of Physiology and Biochemistry

(40th ed.) R. J. S. MCDOWALL, M.D., D.SC., professor of physiology, University of London. London: John Murray. 1950. Pp. 767. 30*s*.

THIS standard textbook is now a hundred years old. William Senhouse Kirkes gave it birth, at Barts, W. D. Halliburton helped to foster it in its maturity, and Professor McDowall has been twenty years at the work of keeping it young. Its name alone is misleading—within living memory it has always been a two-hand book—but in all other respects it is trustworthy, as a long succession of students know.

In spite of the many loud calls for "integration" in the teaching of the preclinical subjects, the current trend in medical schools is to separate biochemistry from physiology by the establishment of separate chairs in the two subjects. Professor McDowall wisely disregards the rift, devoting large parts of his book to topics which are nowadays reckoned to be the province of the biochemist. By presenting the whole subject in one textbook, he teaches the elementary student to judge for himself the relations not only between the different systems of the body, but between the different systems of his professors.

Lord Lister: His Life and Doctrine

DOUGLAS GUTHRIE, M.D. Edinburgh: E. & S. Livingstone. 1949. Pp. 123. 15*s*.

A LIFE of Lord Lister has a special interest for us because in his early days he acted as a reporter to THE LANCET, sending accounts of the surgery lectures of his future father-in-law, James Syme; and it was in this journal that there were waged two famous controversies about Lister—that concerning antisepsis and the conditions in Glasgow Royal Infirmary, in which Lister crossed swords with the board, and the accusations made in letters to the editor that he had unjustly criticised his London colleagues, which appeared after the publication in the press of his off-the-record speech to Edinburgh students when he expected to go to London to succeed Fergusson at King's. Dr. Guthrie's book is less bulky than Godlee's "Life" and, of course, different in nature from the Lister Centenary Exhibition Handbook, published in 1927. He gives a number of new letters, including a photograph of one with uncertain spelling but excellent drawings of a frog and lizard by Joseph Lister aet. 8 years; and another, written in 1878—on which Sir Alexander Fleming comments in a recent number of the *Annals of the Royal College of Surgeons*—which mentions a penicillin mould. Dr. Guthrie makes some asides into medical history, outlining, for example, the development of the Glasgow and Edinburgh schools. The book is a most readable account of a great surgeon.

An Atlas of the Blood and Bone Marrow

R. PHILIP CUSTER, M.D., director, laboratories of the Presbyterian Hospital, Philadelphia. Philadelphia and London: W. B. Saunders. 1949. Pp. 321. £3 15*s*.

Dr. Custer has been studying bone-marrow for 18 years, and this lavishly illustrated volume reflects his preference for histological methods. More than half the 278 illustrations of blood and bone-marrow are photographs of histological sections, and most of the rest are photographs of smear preparations, many of them in colour. There are also 5 coloured reproductions from paintings, including 3 first-class plates of malarial parasites from the National Institute of Health, U.S. Public Health Service. Most of the photographs give a very high magnification—sections at about 1000 times and smears at over 2000 times. The page size allows a picture of $6 \times 8^1/_2$ in., and hence there are reproductions of megaloblasts 2 in. across. It is thus not surprising that few of the colour photographs are really clear; but two of them—one showing marrow in sprue and the other blood in monocytic leukæmia—show how good photographs can be today when everything is just right. The photographs of histological sections are uniformly successful.

On June 29, the patient received his weekly refills—A.P. 500 c.cm.; P.P. 600 c.cm.—and later the same day he consumed an immoderate quantity of fresh fruit. This was thought to be the cause of a violent attack of vomiting which followed soon afterwards, and which was accompanied by sudden dyspnœa. This distressed condition did not last more than an hour, and when the patient was seen next morning he seemed to have fully recovered and was no longer dyspnœic. Physical examination did not reveal any unexpected signs.

Radioscopy a week later, before his next refills, showed that the P.P. had completely disappeared, the A.P. was much larger, and the right lung had almost completely collapsed.

The only explanation for these findings is that air had gone from the peritoneal cavity to the right pleural cavity. This was confirmed by the intrapleural pressures, which were higher than the final readings of the week before.

DISCUSSION

Though the P.P. in this case was not a particularly large one, it must have contained at least 1500 c.cm. of air at the time of the accident, which happened only a few hours after a refill. It is therefore surprising that the constitutional upset was not more profound. The patient was fortunate in that the leakage occurred on the right side, so that the opening in the diaphragm was presumably sealed by the liver, thus averting a diaphragmatic hernia.

Banyai[1] and Sita Lumsden[2] have each reported a similar leakage; Mellies[3] reported a case of rupture of a tuberculous lesion of the diaphragm during P.P. treatment; and Smith[4] reported a case due to defects in the diaphragm. Banyai[5] reported two cases in which the leakage was in the opposite direction—from pleural cavity to peritoneal cavity—and he suggested that the air passed along mediastinal structures traversing the diaphragm. When an A.P. is not already present the diagnosis from a spontaneous pneumothorax would be difficult.

The intraperitoneal pressure must obviously be a factor in the causation of such an injury, but in the present case the resting pressure was not remarkable—+ 10 cm. of water. During an attack of vomiting no doubt this pressure would be very greatly increased.

Laird[6] describes air-containing vesicles projecting from the upper surface of the diaphragm which may sometimes be seen on thoracoscopy in cases with a P.P., and postulates the rupture of such a vesicle as the cause of a pneumothorax during P.P. treatment. In patients with a P.P. it is also not unusual for the outline of the diaphragm to present on radiography a lobulated appearance which may be due to Laird's "vesicles." In the present case the right dome of the diaphragm showed this feature.

Medical Societies

EDINBURGH OBSTETRICAL SOCIETY

Pelvic Tuberculosis in the Female

AT a meeting of the society on March 8, with Dr. É. CHALMERS FAHMY, the president, in the chair, pelvic tuberculosis in the female was discussed.

Prof. CHARLES CAMERON compared genital tuberculosis in the male and in the female. In the male the incidence was 5% of all tuberculous lesions; and in 60% of cases the disease at this site was associated with renal lesions. In the female the incidence of genital tuberculosis was higher, but it was infrequently associated with renal lesions. Because localising symptoms were commonly absent, and because many of these cases were treated surgically in gynæcological wards, genital tuberculosis was seldom seen or diagnosed by sanatorium workers.

Clinically, the condition presented as an isolated tuberculous phenomenon, although there might be a history of pleurisy or of some other transient tuberculous condition. The mode of infection was usually via the blood-stream, although direct involvement from widespread tuberculosis of the peritoneal cavity was possible. Routine endometrial biopsy in cases of sterility brought to light more cases of tuberculous endometritis; and this was almost always associated with tubal involvement. Diagnosis was by no means easy, but it might be aided by culture of the menstrual blood. Genital tuberculosis was a problem to be faced jointly by specialists in tuberculosis and in gynæcology, and there was still much to learn about its diagnosis, pathogenesis, significance, and treatment.

Dr. W. D. A. CALLAM analysed 67 consecutive cases of pelvic tuberculosis. This, he said, was a disease of the child-bearing years. The presenting symptoms were pelvic pain and vaginal bleeding. Amenorrhœa was uncommon, but the incidence of infertility in the series was 84%. In 40% of the patients there was evidence of tuberculosis elsewhere, especially in abdominal organs and lymph-glands and lungs. The common sites of genital involvement were the tubes, uterus, and ovaries, in that order, but in 2 cases the cervix was involved.

With regard to treatment, in 24 (36%) of the cases this was conservative, consisting in advice on diet and general hygiene; and, in the absence of available beds in sanatoria, this had to be carried out in the patients' own homes. Of 43 patients treated surgically, with an operative mortality of 7%, 23 underwent hysterectomy with bilateral salpingo-oöphorectomy, while the remainder had less extensive operations. Follow-up revealed that a further 12% of the patients had died from a tuberculous lesion, while 80% of the survivors claimed good health.

Amongst the conclusions to be drawn from study of this series was the apparently low incidence of genital tuberculosis and the infrequent evidence of associated tuberculosis elsewhere in the body. Without laparotomy, pelvic tuberculosis was difficult to diagnose, but perhaps the newer cultural methods would prove helpful. Therapeutically, the best results seemed to have followed radical surgery. Controlled clinical investigation of the effects of streptomycin and *p*-aminosalicylic acid were urgently required; these drugs might provide the solution to the problem of managing this dread disease.

HUNTERIAN SOCIETY

Diagnosis and Treatment of Phthisis

AT a dinner meeting of the society on March 20, with Dr. W. THOMSON BROWN in the chair, Dr. GEOFFREY MARSHALL and Mr. HOLMES SELLORS opened a discussion on modern trends in the diagnosis and treatment of pulmonary tuberculosis.

Dr. MARSHALL, illustrating the present position in diagnosis, showed that single radiographs could not be depended on to exclude the disease. A repetition and the closest inspection were required before a certain opinion could be given. Similarly a negative report on the examination of a smear of the sputum for tubercle bacilli was quite inadequate; in any doubtful case a culture was an absolute necessity, since this test is far more delicate than a whole series of ordinary smear investigations. Turning to treatment, he showed how important were ordinary routine measures, but how they must be supported by active treatment such as collapse therapy in its various forms. Of the chemotherapeutic agents and antibiotics, streptomycin was of undoubted value in the

Crimes of Violence

Opinions differ just now about almost every aspect of violent crime in our society. Is it commoner than it used to be before the war; or is it less common but more violent? Is it the result of too much discipline in the Army or too little discipline in the fatherless home? Must we blame the brutality of warfare, or the softness of our penal system? Whatever we think about these propositions we all agree that we want less violent crime, and would probably all support the most effective remedy against it, if that could be pointed out to us. The recent debate in the House of Lords showed how many honest and sincere people would like to believe that corporal punishment is such a remedy. "Like to believe" is a fair way of putting it, for the natural impulse of anyone who witnesses or reads of cruelty is to make the punishment fit the crime. When we hear of elderly women coshed, or kicked, or bundled under railway carriage seats, we hate the aggressors quite violently enough to want to do the same sort of things to them. Revenge is sweet; and perhaps to avenge the wrong of another is even sweeter, because it seems so agreeably free from self-interest. Certainly the flogging of criminals delivers many people from a state of angry tension, and restores their peace of mind. If it can be shown, however, that far from being a remedy for violent crime this measure has no effect in reducing it, and may even, in some cases, foster its repetition, then it is surely a duty to curb this impulse and to avenge the oppressed by seeking more telling ways of dealing with the criminal.

A report produced in 1939, by Mr. E. Lewis-Faning, PH.D., of the Welsh National School of Medicine has not been quoted in recent debates. He examined statistically[1] the evidence on which the Departmental Committee on Corporal Punishment based their opinion that such punishment can be justified only (*a*) if a sentence of imprisonment or penal servitude combined with corporal punishment operates more effectively as a deterrent than a sentence of imprisonment or of penal servitude not combined with corporal punishment; and (*b*) if, for some classes of offence sentences of imprisonment or penal servitude are so ineffective as deterrents that it is necessary to add a further penalty containing an exceptional element of deterrence. In his study Dr. Lewis-Faning used the analysis made for the committee of the after-histories of the 440 persons sentenced for crimes of robbery and violence in the ten years 1921–30. He found that first offenders had more chance of escaping this form of punishment than those who had been previously convicted of serious crime; that, at ages 21–30, the subsequent record of persons flogged was definitely worse than of persons not flogged; and that there was no evidence—even in the group with the worst criminal record—that flogging was a successful deterrent against the repetition of crimes of violence.

Suggestive though these findings were, they might still count for little if it could be shown that flogging prevented those who had never experienced it from committing crimes of violence. Accordingly Dr. Lewis-Faning examined the relation between changes in the amount of flogging ordered and changes in the prevalence of this class of crime in the country since 1863. Estimating the number of floggings ordered as a percentage of the convictions, in each of those years, of males between the ages of 15 and 54 for robbery with violence, he matched them against the annual number of these crimes known to the police (judging that there could be very few crimes of this type *not* known to the police). The results were most unexpected: for it was found that the volume of flogging fluctuated quite arbitrarily over the years, and bore no apparent relation to the volume of crime. The violent-crime level behaved much more reasonably. In 1858 the rate of such crimes was 150 per million of the estimated male population between the ages of 15 and 54; in 1864, when flogging figures first became available, it had fallen to 128 per million; and from that point it fell more or less steadily until, in 1910, it had reached only 20 per million; and it stayed round about that level until the survey ended in 1938. The flogging figures were very different. Between 1863 and 1892 they never rose above 18% of convictions, and were often much lower, there was a slight peak of 31% in 1895 (*after*, not during, the 1887–94 outbreak of violent crime in Liverpool), but the figures soon settled again to below 19%, and during the early years of the new century they kept mainly within a range of 1·5–6·0%. In 1914, and again in 1917, no floggings were ordered; and the crime level maintained its even tenour. Then, in 1919, for no reason connected with crime, the flogging-rate rose steeply in a series of unprecedented peaks, reaching in 1933 the astounding figure of over 65% of convictions: and *still* there had been no major change in the crime-rate.

What can be the meaning of this curious phenomenon? It might be argued, Dr. Lewis-Faning notes, that as this type of crime becomes less common it also becomes more abhorrent to the orderly citizen, and that this is reflected in a tendency to punish it more severely. This would be evidence, he says, that corporal punishment is imposed on the retributive principle, but those who advocate it are, of course, hot to maintain its deterrent effect. Another explanation of this rise in the post-war years must surely suggest itself. If war is brutalising, its effects are not confined to one section of the community: none of us is immune from that demoralising experience. The unprecedented and unprovoked rise of the flogging-rate after the 1914–18 war may well have been a measure of such demoralisation; and is it not possible that the same influence is at work now? A taste for the use of the cosh and a taste for the use of the cat may both have been fostered by five years of violence. Small things hint at a general lowering of humane standards—a sermon preached

---

[1] *J. R. statist. Soc.* 1939, 102, 565

The text is less impressive than the illustrations. Dr. Custer has adopted the nomenclature recommended by the recent Clarification Committee, but we are glad to see that he has rejected "rubriblast" and similar terms for erythroblasts. Each section is a cursory account of a group of blood diseases, enlivened by massive but relatively uninformative tables. All of this has been better done elsewhere. The general aim, Dr. Custer says, is to promote accuracy in diagnosis, but the pictures are not arranged in a way to further this end: there are no plates, for instance, representing the various forms of the lymphocyte. Instead the immense compendium illustrates in some way every known blood disease, including many rarities. The only condition omitted seems to be the acute erythræmia of di Guglielmo. Many sections are outstanding—for example the photographs showing the stages of hæmopoietic development in the embryo—but even so the book will be of little use to the general clinician or clinical pathologist. The experienced hæmatologist will value it as a collector's piece, and the pure pathologist will find here information about histological changes in the bone-marrow not to be found anywhere else.

Biology

An Introduction to Medical and Other Studies. P. D. F. MURRAY, M.A., D.SC., professor of zoology in the University of Sydney; sometime university reader in biology, St. Bartholomew's Hospital Medical College, London. London: Macmillan. 1950. Pp. 600. 25*s.*

WRITTEN simply and clearly, this work is just what a really good textbook of biology should be—not merely a compilation of dry descriptions but also comparative and exegetic, with the accent on evolution. Thus, in the description of amphioxus little or nothing is said of what does not help to an understanding of vertebrate structure. Teleology is carefully avoided: "It is not for a textbook of Biology to say whether man's destiny is to live with the angels, but certainly he was born with the apes." The reader's attention is held throughout, from unicellular animals and plants to vertebrates, with the aid of 381 beautifully clear illustrations. The book is written mainly with an eye to the education of medical students; consequently it deals also with such subjects as comparative zoology, histology, embryology, genetics, organic chemistry, physiology of growth and nutrition, and bacteriology. Perhaps we should point out that some of the deductions about Eoanthropus, in the discussion of modern man's fossil ancestry, have been shown to be wrong by the results of fluoride tests published since this book was printed.

Green Thraldom

Essays of a Chinese Biologist. TANG PEI-SUNG, professor of physiology and dean of the college of agriculture, Tsing-Hua University, Peiping. London: Allen & Unwin. 1949. Pp. 127. 12*s.* 6*d.*

THIS delightful series of essays is the work of a man whose varied experiences of life in China, Japan, and the United States—with all the vicissitudes of flight from the Japanese, when they invaded northern China, and translocation of his laboratory to Kunming in Yunnan—have left him still an undaunted biologist and research-worker, and above all a Chinese. The essays can be enjoyed by anyone with an interest in, and a speaking acquaintance with, modern science in the realms of physiology and general biology, and they may also be read with advantage by any specialist; for as might be expected from the land of Confucius, an underlying unifying philosophy runs through them. The theme is that we are still under the thrall of the vegetable kingdom, and the author indicates the slight partial escapes we have made from that thraldom. "Men may hope to become at least partly independent of the green plant, and hence of the land surface, for the supply of raw materials and for the production of food and power." The practically minded person will find in these essays a store of facts and data on the feeding of the nations—particularly the Chinese and Americans—as well as studies of the metabolism of Chinese and American labourers and soldiers. And the philosophically minded, who believes that knowledge is one and indivisible, will meet much to confirm his belief.

Counting Tubes

Theory and Applications. S. C. CURRAN, PH.D., F.R.S.E.; J. D. CRAGGS, M.SC., PH.D. London: Butterworths Scientific Publications. 1949. Pp. 238. 35*s.*

THE Geiger counter originated when Rutherford in 1908 devised a method for detecting the electrical effect of a single alpha particle. The success of his experiment depends upon the phenomenon of ionisation by collision, discovered by Townsend. If an ion, positive or negative, is speeded up in a gas by an electric force, the high-speed ion in its collisions with the neutral gas molecules causes more ions to form and these in turn repeat the process; so we get amplification. Herein lies the secret of the value of the instrument to the physicists, who in the course of forty years have come to use it widely for the detection of minute electrical currents; the counter can then become the detector of radiation—any radiation that can produce an ion. Hospital physicists rely on the counter for a large part of their work relating to methods of protection from X rays and radium, to the distribution of radiation from active sources, and in tracer work with the ordinary radioactive isotopes. About 500 authors have contributed to the advances in theory and application of a most ingenious instrument, and the authors have produced an excellent reference book.

Individual Sports for Women (2nd ed. Philadelphia and London: W. B. Saunders. 1949. Pp. 414. 21*s.*).—This book, by Dorothy S. Ainsworth and six other women members of the staff of the department of physical education at Smith College, encourages the inclusion in school or college physical-education programmes of sports which can be enjoyed alone or with a companion. Such sports are thought to be a social asset for American youth. The eight sections—on archery, badminton, bowling, fencing, golf, riding, swimming, and tennis—are written by experts and helpfully illustrated to show the correct grips and posture, and the general formation of the sport. Instructors or leaders are given much useful advice about equipment. Cheap home-made accessories are described, and practical information given on storage of equipment, arrangement of practice courts, placing of targets, and—in the riding section—care of the horse. Even for a fully trained instructor the book offers useful schemes of progression, and in each section there are valuable hints on class-handling as well as an analysis of common faults. A short history of each game serves as introduction, and references to books or films are listed at the end of each section. The equipment prices quoted are American; but in other ways the book would be useful to those doing club and recreational work in this country.

The World Next Door (London: Gollancz. 1950. Pp. 320. 12*s.* 6*d.*).—This book, the blurb tells us, has "integrated form, breathless drive and a constantly luminous vision." This overpraise may incline the reader to do less than justice to an honest and sincere account of life in an American mental hospital. "The Snake Pit" has stolen some of Mr. Fritz Peters's thunder, and so, in a more subtle but perhaps none the less effective way, has that entertaining play, "Harvey." We all know something now of life in American mental hospitals; we know that some nurses are sadistic and that certification (committal as they call it) can be had for the asking. The hero of this book is depicted as having a very beautiful character. He was however an exceptionally tiresome young man. He irritated his family by his oddness and by taking all his clothes off on the lawn. Trying, one can see, but hardly a sufficient reason for certification. He then irritated the nurses by his literal-minded obtuseness. While this does not justify them in socking him on the jaw, one can see that it might be provoking. Nevertheless, power corrupts, and it is not only great men who tend to be bad when they have the weak at their mercy. This point cannot be made too often.

The hero (like most mental patients in fiction) appears to be suffering from a mixed psychosis. It has some schizophrenic features, including thought disorder; and since it is difficult to describe thought disorder without becoming disorderly, the book gets better as the hero regains his sanity. This book gives a rounder and fairer picture of the good nurses than "The Snake Pit"; but, when it comes to conveying to us the deranged state of mind, Dostoievsky does it better.

THE LANCET

LONDON: SATURDAY, APRIL 8, 1950

Crimes of Violence

OPINIONS differ just now about almost every aspect of violent crime in our society. Is it commoner than it used to be before the war; or is it less common but more violent? Is it the result of too much discipline in the Army or too little discipline in the fatherless home? Must we blame the brutality of warfare, or the softness of our penal system? Whatever we think about these propositions we all agree that we want less violent crime, and would probably all support the most effective remedy against it, if that could be pointed out to us. The recent debate in the House of Lords showed how many honest and sincere people would like to believe that corporal punishment is such a remedy. "Like to believe" is a fair way of putting it, for the natural impulse of anyone who witnesses or reads of cruelty is to make the punishment fit the crime. When we hear of elderly women coshed, or kicked, or bundled under railway carriage seats, we hate the aggressors quite violently enough to want to do the same sort of things to them. Revenge is sweet; and perhaps to avenge the wrong of another is even sweeter, because it seems so agreeably free from self-interest. Certainly the flogging of criminals delivers many people from a state of angry tension, and restores their peace of mind. If it can be shown, however, that far from being a remedy for violent crime this measure has no effect in reducing it, and may even, in some cases, foster its repetition, then it is surely a duty to curb this impulse and to avenge the oppressed by seeking more telling ways of dealing with the criminal.

A report produced in 1939, by Mr. E. LEWIS-FANING, PH.D., of the Welsh National School of Medicine has not been quoted in recent debates. He examined statistically[1] the evidence on which the Departmental Committee on Corporal Punishment based their opinion that such punishment can be justified only (*a*) if a sentence of imprisonment or penal servitude combined with corporal punishment operates more effectively as a deterrent than a sentence of imprisonment or of penal servitude not combined with corporal punishment: and (*b*) if, for some classes of offence sentences of imprisonment or penal servitude are so ineffective as deterrents that it is necessary to add a further penalty containing an exceptional element of deterrence. In his study Dr. LEWIS-FANING used the analysis made for the committee of the after-histories of the 440 persons sentenced for crimes of robbery and violence in the ten years 1921–30. He found that first offenders had more chance of escaping this form of punishment than those who had been previously convicted of serious crime; that, at ages 21–30, the subsequent record of persons flogged was definitely worse than of persons not flogged; and that there was no evidence—even in the group with the worst criminal record—that flogging was a successful deterrent against the repetition of crimes of violence.

Suggestive though these findings were, they might still count for little if it could be shown that flogging prevented those who had never experienced it from committing crimes of violence. Accordingly Dr. LEWIS-FANING examined the relation between changes in the amount of flogging ordered and changes in the prevalence of this class of crime in the country since 1863. Estimating the number of floggings ordered as a percentage of the convictions, in each of those years, of males between the ages of 15 and 54 for robbery with violence, he matched them against the annual number of these crimes known to the police (judging that there could be very few crimes of this type *not* known to the police). The results were most unexpected: for it was found that the volume of flogging fluctuated quite arbitrarily over the years, and bore no apparent relation to the volume of crime. The violent-crime level behaved much more reasonably. In 1858 the rate of such crimes was 150 per million of the estimated male population between the ages of 15 and 54; in 1864, when flogging figures first became available, it had fallen to 128 per million; and from that point it fell more or less steadily until, in 1910, it had reached only 20 per million: and it stayed round about that level until the survey ended in 1938. The flogging figures were very different. Between 1863 and 1892 they never rose above 18% of convictions, and were often much lower; there was a slight peak of 31% in 1895 (*after*, not during, the 1887–94 outbreak of violent crime in Liverpool), but the figures soon settled again to below 19%, and during the early years of the new century they kept mainly within a range of 1·5–6·0%. In 1914, and again in 1917, no floggings were ordered; and the crime level maintained its even tenour. Then, in 1919, for no reason connected with crime, the flogging-rate rose steeply in a series of unprecedented peaks, reaching in 1933 the astounding figure of over 65% of convictions: and *still* there had been no major change in the crime-rate.

What can be the meaning of this curious phenomenon? It might be argued, Dr. LEWIS-FANING notes, that as this type of crime becomes less common it also becomes more abhorrent to the orderly citizen, and that this is reflected in a tendency to punish it more severely. This would be evidence, he says, that corporal punishment is imposed on the retributive principle: but those who advocate it are, of course, hot to maintain its deterrent effect. Another explanation of this rise in the post-war years must surely suggest itself. If war is brutalising, its effects are not confined to one section of the community: none of us is immune from that demoralising experience. The unprecedented and unprovoked rise of the flogging-rate after the 1914–18 war may well have been a measure of such demoralisation: and is it not possible that the same influence is at work now? A taste for the use of the cosh and a taste for the use of the cat may both have been fostered by five years of violence. Small things hint at a general lowering of humane standards—a sermon preached in Winchester Cathedral on Assize Sunday, for example, in which a priest advocated a general return to the beating of children, and enumerated various tools for the purpose. His declared aim was again the suppression of violent crime: he disregarded the fact that in the sections of society from which most violent criminals are drawn a good hiding is still regarded as the appropriate and convenient treatment for a troublesome child.

---

[1] *J. R. statist. Soc.* 1939, 102, 565.

If corporal punishment could check crime, or even a tendency to crime, it has had ample opportunity to prove its worth. The evidence suggests that it is worthless as a deterrent, and dangerous as a corrective. Let us keep our heads and tempers and seek more effective methods of protecting society. An adequate police force, all agree, would be a good start.

Prophylactic Inoculation and Poliomyelitis

THE report from Melbourne which appears on p. 659 is important and disturbing but need not be alarming. A complaint by the parents of children who developed paralytic poliomyelitis soon after a prophylactic inoculation led the Health Department of the State of Victoria to investigate the immunisation history of the 375 cases of poliomyelitis notified during the epidemic in the State between January and August, 1949. Apart from a few who could not be found, the parents of all these cases were asked whether their child had been immunised against diphtheria or whooping-cough, and, if so, when and by whom. Complete histories were obtained for 340 cases, and Dr. BERTRAM MCCLOSKEY, who was responsible for this field investigation, found that 31 had received a prophylactic injection of one kind or another within three months of the onset of poliomyelitis. He then personally obtained the exact dates and the sites of inoculations from the parents, and in all but 4 cases confirmed these from the doctors' records.

Since the frequency of inoculations in comparable age and sex groups in Victoria at that time is not known, this finding of 31 cases of poliomyelitis following inoculation is in itself not remarkable. The significant finding is that there was clearly an association between the site of the last injection and the site and degree of the subsequent paralysis. This was particularly well marked in the children who had received pertussis vaccine, either alone or in combination, but it existed for diphtheria toxoid also. The age of the child is known to be an important determinant of the site and severity of paralysis in poliomyelitis: in younger children there is a tendency for the lower limbs to be affected. But here, whatever the patient's age, the injections into the arm were clearly associated with an increased frequency and clinical severity of upper-limb paralysis. It is suggestive, too, that, if we exclude 2 cases, the intervals between the last injection and the onset of paralysis ranged from five to thirty-two days, limits which correspond closely to the usually accepted incubation period of poliomyelitis. As MCCLOSKEY emphasises, however, all the cases of paralysis following inoculation occurred during a severe epidemic of poliomyelitis. This was almost certainly the determining factor.

It would be premature to discuss the possible mechanism of this association in any detail, but it seems likely that the more obvious sources of infection—contamination of the prophylactic agents or of the syringes—will not explain the facts. No single batch of any one product could be incriminated; those used included some from England, from the U.S.A., and from Australia. It is more probable that this is yet another manifestation of the association between trauma (in its widest sense) during the prodromal period—whether by tonsillectomy or severe exercise or chilling—and the localisation of paralysis in poliomyelitis.

MCCLOSKEY's stimulating observations are, of course, only the beginning of the investigations which must be done before their implications in public-health work can be seen. From the practical point of view, we must be able to balance the known risks run by our patients in facing diphtheria or whooping-cough without the protection of prophylactic inoculation against the risk that inoculation during a poliomyelitis epidemic will render them more liable to paralysis. The Australian findings have not established that injection increases the risk of infection by poliomyelitis, but we must be sure on this point. If this is not the case, and the virus infection attack rates are the same in inoculated and non-inoculated groups of children, we must find out whether injection during the prodromal period increases the liability to paralytic manifestations of the disease. These questions cannot be answered by a retrospective investigation where only the instances of positive association are known; a forward investigation of a cross-section of the child population, whether inoculated or not, would be needed. Extensive field surveys of this kind bristle with difficulties but they are essential if the immunisation campaign is not to be marred by either unjustified optimism or unbalanced gloom. We understand that the Ministry of Health is in touch with these developments and has its own studies of this country's experience well in hand. Their conclusions should be made known as soon as possible.

Streptomycin in Urinary Tuberculosis

THE value of streptomycin in urinary tuberculosis still awaits final assessment. So far experience has been mainly favourable: streptomycin often leads to gratifying clinical improvement but it has serious limitations and has certainly not superseded the usual methods of treatment. The course of the tuberculous process in the urinary tract is insidious and unpredictable and the effect of any treatment should be observed for years before it is accepted as solidly established. The type of disease and its advancement must be well-defined if comparisons between one series and another are to be valid. A single detail of pathology may completely alter the course of the disease and its response to treatment. Thus RINKER[1] has studied the rôle of ureteric involvement in renal tuberculosis and its response to streptomycin. Quite apart from streptomycin therapy, complete occlusion of the ureter is not uncommon in this disease; it may occur temporarily in 10–20% of cases, though it probably remains permanent in less than 1%. RINKER found that out of 6 tuberculous kidneys treated with streptomycin 5 developed temporary occlusion of or an impassable stricture in the ureter, and he takes this to be a manifestation of the healing process promoted by the streptomycin. Ureteric occlusion may obviously have a profound effect on the findings in the bladder urine, which are looked on as indicating the course of the disease; for tubercle bacilli may be absent simply because they are being kept out of the bladder, though they are still active in the kidney. In judging the effect of treatment it is therefore essential to determine whether the urine from the affected kidney is reaching the bladder, and this will necessitate cystoscopy, probably combined with indigo-carmine excretion tests or ureteric catheterisation, or excretion pyelography.

---

[1] Rinker, J. R. *J. Amer. med. Ass.* 1950, 142, 87.

One of the most important conditions for assessing the results of any method of treatment is a control series. It is in this respect that the work reported by A. H. JACOBS and W. M. BORTHWICK to the urological section of the Royal Society of Medicine on March 23, is particularly valuable. They have studied 90 cases of renal tuberculosis at the Robroyston Hospital near Glasgow, half being treated with streptomycin and half without. To toughen the scientific fibre of the investigation, the patients were allotted to their group by Medical Research Council statisticians in London. A defect of the report, which its authors readily admitted, is that it is made only fifteen months after the beginning of the investigation; but the observations are being continued and more mature results will be reported later. In most of the patients the disease of the urinary system was the only or at least the dominant tuberculous focus. In every case the urine was examined by direct smear, by guineapig inoculation, and by culture, though BORTHWICK found that if the smear result was negative the other tests were rarely if ever positive. Instrumental pyelography was done as a routine on both sides, in addition to excretion pyelography. The standard course of streptomycin was 1 g. daily, given in two doses, for ninety days. The incidence of vestibular damage was high, and in BORTHWICK's experience there was no apparent recovery. The development of streptomycin-resistance in the infecting organism was a frequent difficulty and still occurred in spite of the simultaneous administration of *p*-aminosalycilic acid.

In analysing their results JACOBS and BORTHWICK divided their cases into five groups: (1) minor disease in one kidney; (2) major disease in one kidney treated by nephrectomy, with persisting cystitis; (3) bilateral disease in which one kidney is only slightly involved and the other has been removed; (4) tuberculosis developing in a previously healthy kidney after the other has been removed for tuberculosis; and (5) bilateral disease unsuitable for operation. In the first group the tubercle bacilli disappeared from the urine under treatment with streptomycin in all but 1 case but by the end of six months they had reappeared in half the cases. Streptomycin did not prevent involvement of the healthy kidney in nearly half the cases, but it seemed to reduce the incidence of cystitis, since this complication developed in only 1 treated patient but in 4 of the controls. In the second group the most obvious effect of streptomycin was in relieving the cystitis, which it did in 11 out of 14 cases. In over a quarter of the treated cases in this group the urine became T.B.-negative, and in the third group half the treated cases responded, similarly. The fourth group comprised only 6 cases, and the 4 treated with streptomycin all had severe cystitis; 1 of these 4 became T.B.-negative, 1 died, and in 2 the frequency became worse. This adverse effect on the symptoms of cystitis was very striking in these and one or two other cases. It may be attributed to the fibrosis accompanying healing and is closely allied to the formation of strictures in the ureter, observed by RINKER. The fifth group included two very different types of case: (*a*) those with major disease on both sides in which surgery was out of the question; or (*b*) those with very slight lesions on both sides. In type (*a*) streptomycin had little effect and did not prevent 2 deaths in the 8 cases. Taking the series as a whole, the conclusions reached were that streptomycin has no effect in established ulcerocavernous disease; in unilateral disease nephrectomy should remain the standard treatment but streptomycin may help both before and after operation; and streptomycin is of great value in relieving secondary cystitis, though the primary kidney lesion must be small if it is to be fully successful.

Annotations

FILM ON DEOXYCORTONE

LAST week a new film *Rheumatoid Arthritis: Some Cases Treated with Deoxycortone and Ascorbic Acid* was shown to the press in London. This film, made with Mr. David Le Vay and Dr. Geoffrey Loxton as medical advisers, does not (it is stated) set out to show the value of these compounds in therapy but is intended merely to demonstrate what happens—or what may happen—when deoxycortone and ascorbic acid are given. Of the 7 patients who are included, 1 is shown six weeks after the start of twice-weekly injections, but otherwise the film compares the state before and half an hour after an injection. "The patients were selected," the accompanying résumé tells us, "only to the extent of their willingness to be photographed; subject to this they were consecutive cases." In all 7 cases the range and speed of movement was apparently increased; and the film shows clearly that in a given patient the improvement is not always equal in all joints, and that in a given joint some movements may be improved much more than others. The makers concede that dosage is not yet settled; that it is uncertain whether all patients will respond as these 7 were shown to respond; and that whether the combined treatment will continue to exert a beneficial effect when given for long periods has yet to be established. Their object is simply to record what they have seen: this, they say, is a research film.

This being so, the wisdom of releasing it generally among the profession must be seriously questioned—even if, as is proposed, it is used by rheumatologists simply to illustrate lectures. There is, we fear, a real risk that this record of immediate effects will gain for the technique closer friends than it has so far been proved to deserve. What is quite certain is that it will convert none of the sceptics, who seem still to include a majority of clinicians with wide experience of rheumatism, and particularly those with experience of 'Cortisone' and adrenocorticotropic hormone. One shot seems to show diminution in joint swelling half an hour after a single injection; but otherwise there is hardly any objective evidence to change the mind of those who attach weight chiefly to the psychological effect of this novel method. The opportunity to include control observations, which might have met this objection, has unfortunately not been taken.

On one point there will be no argument—namely the technical brilliance of the production, by Dr. Brian Stanford. The film, which is 16 mm., in colour, and runs for about 16 minutes, has been made for Messrs. Ciba Ltd.

THROMBOCYTOPEN

It has always been surprising that though removal of the spleen causes so striking a remission of primary thrombocytopenic purpura, no really significant structural changes in the spleen have been found. The possibility that the spleen was producing some platelet-destroying substance was soon thought of. Torrioli and Puddu [1] in 1934 discovered that an extract made from the spleen removed from a patient with thrombocytopenic purpura injured the megakaryocytes in cultures of guineapig bone-marrow; a similar extract of a normal spleen and of various other organs showed the presence of this antimegakaryocytic substance, though in lower concentrations. Later [2] they prepared a protein-free extract of a normal spleen, injected it intravenously into rabbits, and showed that there was a definite lowering of the platelet-count in the peripheral blood; they produced some evidence that blood from the splenic vein contained more of this platelet-reducing factor than blood from the splenic artery. So there seemed to be some ground for supposing that in primary thrombocytopenic purpura the spleen produces an excess of a platelet-reducing substance; and this, at least, provided a rational explanation for the success of splenectomy.

Troland and Lee [3] used an acetone extract of spleens. They found that extracts from the spleens of three patients with thrombocytopenic purpura injected intravenously into rabbits caused a sharp reduction of the blood-platelets, but they could not demonstrate any activity in spleens of patients with hæmolytic anæmia or Banti's syndrome, or in extracts from normal spleens. So far as the evidence went, it supported the splenic secretion theory, and Troland and Lee named this unidentified substance "thrombocytopen." In 1941 we commented [4] that evidence both confirming and denying the existence of thrombocytopen had appeared and that the subject remained unsettled. Up to the present, though different methods of preparing the extracts have been tried, and different test animals used, still no finality has been reached, because about as many observers denied the existence of thrombocytopen as could find it, and about an equal number obtained equivocal results.

A new approach has been tried by Singer and Rotter.[5] They argued that if thrombocytopen was formed in the spleen, it would, in the natural course of events, go first to the liver and might there be inactivated; the inconsistent results obtained so far might depend on how much inactivation took place in the liver of the test animal. If so, then the best test animal would be one whose liver was considerably damaged. They therefore used male albino rats which were given two intraperitoneal injections of 0·5 mg./kg. of carbon tetrachloride; this dose caused a suitable degree of liver damage, but only minor kidney damage. They prepared suspensions of spleens and other organs by freezing the tissue, then defrosting and mixing the chopped tissue with saline. The freezing and defrosting process employed damaged red blood-cells and consequently some of their test animals developed hæmoglobinuria; but it was found that injections of red cells alone did not affect the platelet-count. With this technique, they were able to show that a platelet-lowering substance is present in the suspensions of many different organs including spleen, lung, heart, kidneys, and brain. Normal human spleens and those from patients with primary and secondary thrombocytopenic purpura, and from patients with other blood diseases who had normal platelet-counts, all contained thrombocytopen in about the same concentration. Singer and Rotter were also able to extract with ether the platelet-reducing substance from normal human urine and from the urine of thrombocytopenic patients.

These results make it reasonably clear that there does exist a platelet-reducing substance in organ extracts. But no specific connection with thrombocytopenic purpura has been found. Thrombocytopen thus joins the list of splenic substances having some action on blood-clotting; others are the "splenins" described by Ungar [6]—splenin A which increases the bleeding-time of guineapigs, and splenin B which has the opposite effect—and Moolten's "thrombocytosin" which increases the platelet level.[7] Whether any of these agents has any rôle in the physiology of blood-clotting or platelet production and function is doubtful; Singer and Rotter do well to remind us how difficult it has proved to fit that powerful anticoagulant heparin into any scheme of normal blood-clotting.

WHERE DO WE GO FROM HERE?

Those who attend conferences on mental health occasionally feel that great truths and broad principles, however well they nourish the spirit, are not entirely sustaining to ordinary psychosomatic man. He needs his halfpennyworth of bread, even though he does not live by bread alone; and he is even, at times, ready to risk his digestion on a handful of brass tacks. Professor Alexander Kennedy, who consumes brass tacks with relish, hinted, when presiding on the first day of a conference [8] on "Mental Health and the Family," that perhaps our behaviour is not entirely determined; and that it is even possible that the process of evolution may become orderly if we apply common sense and plain English to it. The Archbishop of Canterbury, in opening the conference, also declared for plain English, exhorting psychiatrists to be distrustful—or at least careful—of words. We can make them mean too much, he said; and we can use multitudes of them to mean too little—the more tired we get the more we take refuge in words; and in this we are abetted by the dreadful facility of the secretary and the typewriter. Again, all words are shorthand, but the shorthand of a particular discipline may be too short for good sense: he quoted the term "psychosocial medicine," as an example. He was naturally undisturbed by the notions that man's behaviour is entirely determined, or that God is a projection of the unconscious mind; and he felt that many scientists now shared his confidence. But when psychiatrists, as he said, explore and play about with religion as an aspect of man—which is quite the right thing to do, at one level—they are in some danger of thinking that religion has no relation to any eternal reality. Dr. Alfred Torrie, later in the discussion, remarked that any psychiatrist who professed religious principles was in danger of being told by his colleagues that he was not quite grown up. Dr. J. L. Halliday, in his address on social health, cautiously acknowledged the dynamic effect on society of man's religious projections, but was willing also to concede the possible existence of an "Outer and Beyond." He dealt much with the determinants of human behaviour, however, and it was hard to feel he had much confidence in free will. Professor Kennedy doubted whether it is wise—even if it should prove to be true—to believe that unconscious motives so overwhelm our conscious designs that we can compass nothing at all. That bit of free will, that bit of conscious mind, he said, is precious. And indeed it is our only tool in a world where the children of men live—as more than one speaker hinted—in the midst of perennial inner and outer conflict.

[8] On March 23 and 24, arranged by the National Association for Mental Health.

Adolescents are exposed to a particularly bewildering conflict of values. As Dame Olive Wheeler put it, they have great difficulty in achieving mental and moral health, not because of any lack in themselves, but because home, school, workshop, nation, and church do not speak with the same voice. There is no clear witness in their surroundings of an accepted or acceptable ethical code. They are left floundering at a time when they are making their most critical choices.

On the whole, the conference only formulated our problems; it would be useful to know in plain English, as Professor Kennedy would say, what exactly is being done about them—what proportion of parents are taking enlightened behaviour into the nursery, what schools are educating citizens rather than examination candidates, what approved schools and prisons can boast of reform, what industries are fostering higher ethical standards—in short, how common sense is being applied. Perhaps this might be the subject of the next conference.

POLIOMYELITIS IN SCOTLAND

So long as poliomyelitis remains an unpreventable disease with no causal treatment, the problems of its epidemiology will continue to be an absorbing challenge to all interested in public health. In a survey[1] which we have already briefly noticed[2] Dr. Ian Sutherland, a senior medical officer of the Department of Health for Scotland, has provided a detailed and valuable analysis of the Scottish experience of the 1947 epidemic in Great Britain. In essence it consists of 28 tables of statistics with a commentary on their significance. Each table represents a rearrangement of the information on 2002 case-summary cards. Each summary card is a record of some 30 to 50 facts about each person notified as suffering from poliomyelitis in Scotland between June 1, 1947, and Jan. 3, 1948. These essential details were obtained by the medical officers of health, presumably not without much painstaking effort by their indispensable and still underpaid backroom girls—i.e., health visitors.

Of the 2002 notifications, 626 (31·3%) proved to be not poliomyelitis. The most frequent diagnoses of those "not poliomyelitis" were "no abnormality" (14·2%) and tonsillitis (9·9%). Respiratory disease (27·0%), diseases of the nervous system (18·7%), and diseases of the locomotor system (14·7%) account for nearly two-thirds. The over-all incidence was 2·68 per 10,000 (1 in 3731) with an over-all mortality of 8·87%. The maximum incidence was at one year of age—namely, 20·16 per 10,000 (1 in 496). Of those with paralysis 9% needed respirator treatment and almost two-thirds of these died. There was a male-to-female incidence ratio of 1·45 to 1. About one in four with poliomyelitis had no paralysis, but the proportion was higher in rural districts, higher age-groups, and (especially in younger children) in the later stages of the epidemic. The incidence of poliomyelitis compared with "not poliomyelitis" was significantly associated with (1) more apartments, especially four or more, (2) fewer occupants, (3) higher social class in age-groups over five years, (4) better sanitation, (5) a record of associated cases, and (6) pregnancy. Greater severity, shown by the need for respirator treatment or case-fatality was associated with (1) a shorter interval between onset and notification, (2) increasing age, (3) more apartments, (4) fewer occupants, (5) better sanitary conditions, (6) higher social class. There was no significant association between severity and pregnancy. Of 14 pregnant women 4 died, compared with 12 of 84 non-pregnant women of the same age-groups—a difference which could be expected to occur by chance about once in six times.

In his concluding paragraph Dr. Sutherland writes: "No attempt is made to sum up the observation of the survey in one or two sentences. In fact the survey will have served a useful purpose if it reinforces the danger of categorical statements which, on closer study, demand such modification or amplification that the original simplicity is shown to be false." But a table giving the statistical findings for each association tested would itself have been a summary and a great help to those not actually preoccupied with the epidemiology of poliomyelitis. In sum, however, the survey provides admirable building material, and the author seems well justified in hoping "that the detailed description, when compared with others elsewhere, will help to establish the common features of this serious infection and, with the development of techniques of confirmation of infection, eventually lead towards better techniques of study and control."

CONSTITUTIONAL CHANGES

CONSTITUTIONAL reform seems to be in the air. The House of Lords, the General Medical Council, and now the council of the British Medical Association have all been considering whether their membership should not change with the changing times. On March 29 at a special representative meeting of the B.M.A., Dr. J. A. Pridham, chairman of the organisation committee of the council, explained that during the negotiations before the National Health Service Act was passed they came to realise that the link between the council and the divisions and branches was not close enough. The council should at once know the needs and wishes of the branches and divisions and keep them informed of what was "cooking" at headquarters. The directly elected members of council would find it easier to do this if their constituencies were of more manageable size. It was therefore proposed to increase their number from 22 to 39. But though the council agreed on the need for more directly elected representatives they were also agreed that to increase the total membership of council would be to render it ineffective, and they were faced with the necessity of making economies somewhere. They therefore reluctantly suggested that the number of ex-officio members should be reduced and that the number of members elected by the representative body should be reduced from 20 to 13, mainly by discontinuing the system of election by group representatives. Dr. H. G. Dain put the point of view of those who opposed these changes. He feared that they would endanger the representative body's control of council. They should be able, he declared, to choose people and not be tied down by areas. To make council a second parliament would detract from the authority of the representative body. He also made the point that the present council contains representatives of all types of practice. This balance, he felt, might be less easy to attain if more members were elected from the periphery. The council's proposals[1] were, however, ultimately passed with one amendment—namely, that the deputy chairman of the representative body was retained as an ex-officio member.

In the afternoon the discussion on the constitution of council was interrupted to consider a series of resolutions on the relationship to the association of the autonomous bodies—the General Medical Services Committee and the Central Consultants and Specialists Committee. Lord Horder spoke eloquently for those who viewed their existence with anxiety. He was uncertain of the difference of meaning between autonomous and independent. There was a danger that the representative body might emasculate itself by continuing to add these bodies. Disaster could be avoided only if the repre-

As regards school-children, we recognise the risks attached to school life, when the child is trying to adapt himself, physically and mentally, to life outside the family. It is during school life that the child learns to stand on his own feet and gains an impression of the tasks ahead of him throughout life. The task of helping him can best be carried out by close coöperation between parent and teacher. The school medical officer should play his part in keeping the teacher up to date on health matters, and it would be a good scheme to have one teacher in every school specially interested in health education. Recently, at the Institute of Education, attached to the University of Bristol, a special course on public health was organised for those teachers in the training colleges who are responsible for teaching health education. We hoped to give them first-hand experience of public health in practice and thus make it easier for them to teach their subject. Group conferences are valuable but do not take the place of personal contact between the parent and the teacher. All these methods of tackling the problem help, but it is of prime importance that the parent and the teacher shall confer regularly on the question of the child's upbringing

Puberty and adolescence are periods of life when the individual requires special assistance. Again the parent is the best guide. The health visitor, the teacher, and the family doctor can help, but in my opinion they should not come between the child and his parent. Alas, sometimes there is no parent, or perhaps he or she is useless. In these cases a suitable substitute must be found.

SEX EDUCATION

On the question of sex education, training in biology in the school should supply sufficient knowledge to a child, so that with little further instruction—preferably from the parent by a private personal discussion—he himself can understand his personal problems. It is, moreover, most important that such problems should be tackled and dealt with adequately. It should be part of any health-education scheme to prepare parents and teachers for questions which will be asked by the children when these problems appear. I am convinced that sex lectures to classes in senior schools often do more harm than good. I am reminded of an old Welsh story :

> The headmaster of a village school used to give a word of advice to his leavers ; he believed it helped them to know what to do and what not to do when they had left school and had to fend for themselves. On one occasion he told a class of boys about the importance of kindness to animals—it was his pet subject. As an example of cruelty he told how once he saw a boy dropping peas into the ears of the miller's donkey. Now, imagine his surprise when he found out that, instead of deterring the boys from doing the same thing, he had actually put the idea into the heads of two or three of them. These two or three tried the experiment for themselves, to see what would really happen.

Too frequently, I fear, sex talks of that kind merely arouse the curiosity of the child and do more harm than good.

HEALTH PROBLEMS OF ADULTS

As regards the personal health problems of the adult, we all hope that in future the family doctor will have enough time to be also the family friend and adviser. But the need for special advice should be the exception rather than the rule. With a happy home, healthy conditions under which to work, the right use of leisure, and common sense to guide, most human beings can undertake the journey through life without leaning on outside help. A healthy adult does not need expert medical knowledge to maintain his fitness and lead a healthy life. There is no need for him to qualify as a doctor or a nurse—in fact, life tables prove that he would shorten his life by so doing ! What he wants is a sound knowledge of elementary biology : he must know the capabilities of his own body, and how to use his reason, and must have available an occasional word of advice on personal problems that arise.

OLD AGE

We hear a good deal today about the burden of old age. In actual fact we are told that roughly only one in thirty of the aged people are so unhealthy and so dependent as to need special care. But many of these could have been, and can still be, saved from this dilemma and so claim their independence. How much suffering, of which we may never hear, many of the remaining 29 are bearing in silence. There is no doubt at all that there is a big field of prevention in old age. A simple example : the gradation of physical effort as old age advances would prolong the useful period of life in many cases. But perhaps the mental aspect of this problem is the most difficult, for by the time a person has reached this stage of life he is very much a creature of habit. It is sometimes as dangerous to try to correct life-long habits as it is to try to inculcate new ones.

Retirement from active work may be a great danger to health in the later years of one's life. During my association with public life I have seen useless old age strike down councillors and aldermen when they were retired to make room for the younger generation. This must also often happen in industry. Surely there should be no competition here. Can it be that there is no way to occupy the older people without hindering recruitment of the younger generation into public life ? The late Sir Humphry Rolleston had suggestions to make[1] :

> "Retirement is a problem beset with anxiety and danger ; a successful business man when relieved of routine and able to indulge in idle luxury and, without hobbies may rapidly degenerate. He now has to find occupation to kill time instead of time to do all he must ; he begins to feel that 'his day is done,' that he has little but his dinner to look forward to, and that at last he is old and a 'has been.' Thus auto-suggestion, even if not helped by suggestion from outside, hurries him on the downward path ; any trifling ailment, such as rheumatism or indigestion due to over-feeding, may arouse very hypochondriacal anticipations, and observation of contemporaries with premature senile changes may feed the flame of this destructive auto-suggestion. There is, therefore, a basis for the idea that senility is catching, and for seeking the companionship of the young and thereby letting auto-suggestion work in a constructive direction. A well-occupied mind, a happy disposition that thinketh no evil, naturally smiles instead of frowning on a stranger or a new idea, free from anger, hatred, and jealousy, the vice that gives no pleasure to anyone, and an attitude of charity in its original and best sense to all, tend to prolong life and make it a happy, healthy prelude to crossing the bar. In Sir James Crichton-Browne's words, 'the best antidote against senile decay is an active interest in human affairs, and those keep young longest who love most.'"

EPILOGUE

We are told that people in this country are much healthier today than they used to be. If we evaluate health statistically according to the death-rate, the number of cases of infectious disease, and the amount of morbidity, we can come to no other conclusion. But is that the whole story ? As doctors, we look at life and its problems from one direction. We think that the greatest, if not the only, worry that can enter any home is sickness. Of course, when we visit the home that is so, and everything else is pushed aside so that we may get on with our job. But sickness is only an incident—there are many day-to-day worries and tasks which occupy the attention of the home. In the struggle with these, good health in mind and body is a great asset. But it is whether or not these obstacles are overcome and what impressions the struggle leaves on the mind and body that decide in the end whether or not life has been worth living.

HEALTH SERVICE ACCOUNTS

THE system of control and accounting in the National Health Service is examined by the Comptroller and Auditor-General in his report on the civil appropriation accounts for 1948–49.[1]

REGIONAL BOARDS

The report draws attention to an important difference between the practice of the regional hospital boards in England and Wales and in Scotland. Whereas in England and Wales management committees submit separate estimates (which may be curtailed by the boards), in Scotland the boards exercise direct and continuous control of current expenditure and incorporate the accounts of all their management committees in their own accounts; and they have their own auditors to conduct a running review of the committees' expenditure. "The direct and early knowledge of local circumstances available to the Regional Boards as a result of this audit is expected to enable them to correct promptly any extravagant practices"; and it should also assist them materially in their examination of the management committees' estimates.

The first estimates were founded on expenditure in 1946, and in the absence of uniform costing data or statistical information, examination of these estimates could not be based on the comparisons and other checks which are normally relied on for effective budgetary control.

> "Regional boards thus appear to have had little basis either for critical examination of the estimated maintenance expenditure or for judging the relative priority of the numerous capital schemes proposed by some Committees. These conditions to some extent continued to vitiate comparison for 1949–50."

Regional boards have represented that adequate examination of estimates is further hampered by the short time allowed in order to comply with Parliamentary estimates procedure. Some have also expressed the view that the absence of power for them to regulate management committees' establishments has led to excessive staffing and duplication of posts between committees and boards. The treasurers of the boards in England and Wales, in response to an invitation from the Ministry, have made suggestions for strengthening financial control which would bring the system closer to that in Scotland. "The Ministry consider, however, that most of these would be inconsistent with their policy of delegating responsibility to the Committees."

> "The Departments adopted the system of approved budgets as a means of retaining control over total expenditure while giving a reasonable degree of freedom and responsibility to their agents. . . . They see no reason . . . to suppose that when the system has had time to settle down it will not be effective or will lead to extravagance and waste. They consider that, in the long run, dissemination of information of establishments and costs among the hospital authorities themselves, coupled with investigation of particular cases, is likely to provide a more effective check than an attempt to control detailed items in advance. To this end arrangements are being made to instal appropriate costing schemes."

EXECUTIVE COUNCILS

The report states that examination of the records of payments made to general practitioners by executive councils in the period from July 5, 1948, to March 31, 1949, suggests that net earnings as a whole exceeded the Spens (1939) rates by appreciably more than 20%.

> "In particular, the proportions of doctors receiving over £2000 and £2500 (plus betterment) respectively appeared to have been considerably higher than those suggested in the Spens Report. The Departments inform me, however, that they have at present insufficient information as to actual expenses to judge whether the allowance made for these in arriving at the net incomes is adequate. For this reason, and because of the special circumstances prevailing during the initial period, the results of this period by themselves are not considered to justify precise conclusions. They propose to obtain more detailed information of earnings in the year ending 31 March, 1950."

As to the remuneration of dentists, summaries of payments authorised by the Dental Estimates Boards to some 6000 dentists in the period from Oct. 1, 1948, to March 31, 1949, show that about 59% were earning from the N.H.S. at a rate above that intended for full employment therein. Some 1300 (22%) received from the N.H.S. alone gross incomes exceeding £6000 a year. These would be equivalent to over £2880 net if expenses continued at the estimated rate of 52%, or more if, as is probable, expenses did not increase proportionately to fees. Figures recently furnished by the Dental Estimates board for Scotland for the year ended last October suggest that many dentists are still obtaining remuneration much in advance of the Spens scale. Of 688 single-handed dentists the gross fees approved for 138 (20%) were over £6000, and for 7 (1%) were over £12,000. These figures do not take into account the interim cut in earnings over £400 a month, but they include some work at the reduced fees.

Disabilities

49. FACIAL INJURY

WAR-SCARRED London has many reminders of the years 1939–45, but besides its buildings there are many human beings who have outward scars, for show. Many people are very conscious of these scars, for a disfigured face is always noticeable to some extent.

I was one of those unfortunate people who suffered from the flying bombs, having fragments of plate-glass embedded all over the left side of my face and various other parts of my body. However I can now take my place in the world and work for my living like any other normal being. All this has been due to the skill of the plastic surgeon who has rebuilt my face.

In front of me as I write I have a series of photographs, the first taken four days after I was injured. The transformation has been slow (it is now only just a year since I had my last operation, and I was a casualty in 1944); so patience is an essential part of the process of reablement. I was never one of nature's beauties, nor did I ever hope to be, but the face is an integral part of the character of any woman. One's whole attitude to life can be changed by one's appearance.

I never asked for sympathy from anyone; and it seemed to me that if I was going to enjoy my life I had to be cheerful. Nothing can be gained by going about with a long face and carrying eternal hatred in one's heart.

Altogether, I have been in hospital twelve times over a period of 5½ years, and each time another stage has been reached. Apart from losing my left eye, I had suffered severe damage to the right one, and I was almost blind for about 8 months. I had to rely on friends to take me out of doors for exercise. But I never gave up hope of being able to see more one day, and I had to learn to be patient, which was not one of my strong points.

While I was lying in bed during my first spell in hospital I felt I must do something to occupy the time; having been, before my accident, an expert knitter, I decided to try knitting again. Dish-cloth cotton and needles were brought in and I started! Imagine my joy when I found that I could knit very well without seeing. From dish-cloths I progressed and soon I was able to make all sorts of small garments. During my first convalescence I made baby garments and so earned pocket-money.

As regards school-children, we recognise the risks attached to school life, when the child is trying to adapt himself, physically and mentally, to life outside the family. It is during school life that the child learns to stand on his own feet and gains an impression of the tasks ahead of him throughout life. The task of helping him can best be carried out by close coöperation between parent and teacher. The school medical officer should play his part in keeping the teacher up to date on health matters, and it would be a good scheme to have one teacher in every school specially interested in health education. Recently, at the Institute of Education, attached to the University of Bristol, a special course on public health was organised for those teachers in the training colleges who are responsible for teaching health education. We hoped to give them first-hand experience of public health in practice and thus make it easier for them to teach their subject. Group conferences are valuable but do not take the place of personal contact between the parent and the teacher. All these methods of tackling the problem help, but it is of prime importance that the parent and the teacher shall confer regularly on the question of the child's upbringing

Puberty and adolescence are periods of life when the individual requires special assistance. Again the parent is the best guide. The health visitor, the teacher, and the family doctor can help, but in my opinion they should not come between the child and his parent. Alas, sometimes there is no parent, or perhaps he or she is useless. In these cases a suitable substitute must be found.

SEX EDUCATION

On the question of sex education, training in biology in the school should supply sufficient knowledge to a child, so that with little further instruction—preferably from the parent by a private personal discussion—he himself can understand his personal problems. It is, moreover, most important that such problems should be tackled and dealt with adequately. It should be part of any health-education scheme to prepare parents and teachers for questions which will be asked by the children when these problems appear. I am convinced that sex lectures to classes in senior schools often do more harm than good. I am reminded of an old Welsh story :

> The headmaster of a village school used to give a word of advice to his leavers ; he believed it helped them to know what to do and what not to do when they had left school and had to fend for themselves. On one occasion he told a class of boys about the importance of kindness to animals—it was his pet subject. As an example of cruelty he told how once he saw a boy dropping peas into the ears of the miller's donkey. Now, imagine his surprise when he found out that, instead of deterring the boys from doing the same thing, he had actually put the idea into the heads of two or three of them. These two or three tried the experiment for themselves, to see what would really happen.

Too frequently, I fear, sex talks of that kind merely arouse the curiosity of the child and do more harm than good.

HEALTH PROBLEMS OF ADULTS

As regards the personal health problems of the adult, we all hope that in future the family doctor will have enough time to be also the family friend and adviser. But the need for special advice should be the exception rather than the rule. With a happy home, healthy conditions under which to work, the right use of leisure, and common sense to guide, most human beings can undertake the journey through life without leaning on outside help. A healthy adult does not need expert medical knowledge to maintain his fitness and lead a healthy life. There is no need for him to qualify as a doctor or a nurse—in fact, life tables prove that he would shorten his life by so doing ! What he wants is a sound knowledge of elementary biology : he must know the capabilities of his own body, and how to use his reason, and must have available an occasional word of advice on personal problems that arise.

OLD AGE

We hear a good deal today about the burden of old age. In actual fact we are told that roughly only one in thirty of the aged people are so unhealthy and so dependent as to need special care. But many of these could have been, and can still be, saved from this dilemma and so claim their independence. How much suffering, of which we may never hear, many of the remaining 29 are bearing in silence. There is no doubt at all that there is a big field of prevention in old age. A simple example : the gradation of physical effort as old age advances would prolong the useful period of life in many cases. But perhaps the mental aspect of this problem is the most difficult, for by the time a person has reached this stage of life he is very much a creature of habit. It is sometimes as dangerous to try to correct life-long habits as it is to try to inculcate new ones.

Retirement from active work may be a great danger to health in the later years of one's life. During my association with public life I have seen useless old age strike down councillors and aldermen when they were retired to make room for the younger generation. This must also often happen in industry. Surely there should be no competition here. Can it be that there is no way to occupy the older people without hindering recruitment of the younger generation into public life ? The late Sir Humphry Rolleston had suggestions to make[1] :

> "Retirement is a problem beset with anxiety and danger ; a successful business man when relieved of routine and able to indulge in idle luxury and without hobbies may rapidly degenerate. He now has to find occupation to kill time instead of time to do all he must ; he begins to feel that 'his day is done,' that he has little but his dinner to look forward to, and that at last he is old and a 'has been.' Thus auto-suggestion, even if not helped by suggestion from outside, hurries him on the downward path ; any trifling ailment, such as rheumatism or indigestion due to over-feeding, may arouse very hypochondriacal anticipations, and observation of contemporaries with premature senile changes may feed the flame of this destructive auto-suggestion. There is, therefore, a basis for the idea that senility is catching, and for seeking the companionship of the young and thereby letting auto-suggestion work in a constructive direction. A well-occupied mind, a happy disposition that thinketh no evil, naturally smiles instead of frowning on a stranger or a new idea, free from anger, hatred, and jealousy, the vice that gives no pleasure to anyone, and an attitude of charity in its original and best sense to all, tend to prolong life and make it a happy, healthy prelude to crossing the bar. In Sir James Crichton-Browne's words, 'the best antidote against senile decay is an active interest in human affairs, and those keep young longest who love most.' "

EPILOGUE

We are told that people in this country are much healthier today than they used to be. If we evaluate health statistically according to the death-rate, the number of cases of infectious disease, and the amount of morbidity, we can come to no other conclusion. But is that the whole story ? As doctors, we look at life and its problems from one direction. We think that the greatest, if not the only, worry that can enter any home is sickness. Of course, when we visit the home that is so, and everything else is pushed aside so that we may get on with our job. But sickness is only an incident—there are many day-to-day worries and tasks which occupy the attention of the home. In the struggle with these, good health in mind and body is a great asset. But it is whether or not these obstacles are overcome and what impressions the struggle leaves on the mind and body that decide in the end whether or not life has been worth living.

---

1. Rolleston, H. Aspects of Age, Life, and Disease. London, 1928.

undoubtedly have a useful function to perform in addition to the supervision carried out by doctors and midwives." As to the domiciliary midwifery service, some time elapsed before midwives appreciated that the maternity medical service (giving every expectant mother the opportunity of supervision by a doctor antenatally and postnatally, and his attendance at the confinement if necessary) does not place them in the position of maternity nurses; "and in some areas the position is not yet clearly appreciated by the professions."

The new administration has brought under control diverse, though related, services without serious disturbance in their functioning. Already, says the report, some branches of the service were providing facilities which were better and more readily available than before—for example hearing-aids for the deaf.

EPIDEMIC DISEASES

Influenza.—The outstanding epidemiological feature of 1948 was the absence of epidemic influenza. In the first quarter of the year deaths from this cause in the great towns numbered only 280—by far the fewest ever recorded—and it is doubtful whether influenza virus was responsible for any of these deaths since in no instance was influenza virus recovered in the laboratories.

Smallpox.—For the third time in a decade there were no importations of smallpox. "Nevertheless, our experience in 1947 . . . emphasises the importance of applying strictly the well-tried methods for the control of smallpox, whenever its presence is even suspected." The repeal of the Vaccination Acts by the National Health Service Act was followed by an alarming decline in infant vaccination; and the proportion of infants primarily vaccinated during the second half of 1948 was no more than 20%. In 1940 the corresponding rate was 31·5%, and in 1946 it was 41·6%, the average for the ten years 1937–46 being 36·8%

> "It is impossible," Dr. E. T. Conybeare writes, "at present to be certain of the causes of this substantial decline in the acceptance of infant vaccination. The outcome of any introduction of smallpox into this country now depends to a great extent on whether the disease is detected during the first generation of cases, and also on the degree of movement of infected persons before they are diagnosed and isolated. Prompt detection and isolation of smallpox patients cannot be guaranteed, and the greater the decline in the acceptance of routine infant vaccination the heavier becomes the responsibility of those called upon to decide about the policy of recommending general vaccination in dealing with a smallpox outbreak in the initial stages, when its source and full extent may be uncertain. Where, as in Glasgow during 1942 and again in New York during 1947, the populations exposed to infection were very large the wisdom of the decision to recommend general vaccination in the face of an outbreak of smallpox which had escaped detection and control in the earliest stage can hardly be questioned."

Dr. Conybeare goes on to remark that it does not seem to be realised widely enough that the vaccination of a civilian population is now increasingly affected by international considerations as well as by those which are national or individual. There is no young infant for whom parents may be sure that in future there will be no obligation to undertake military service or to travel abroad. "If, as is generally believed, primary vaccination can be most easily and safely performed in infancy then it becomes the duty of parents to see that it is not postponed to a later age."

And the chief medical officer remarks:

> "The National Health Service Act provided, at the instance of the negotiating body, that local health authorities should invite every practitioner engaged in general medical services to play his part in maintaining an adequate state of immunity against smallpox in the population, and it is hoped that family doctors will do their utmost to correct this serious gap in our defences against this pestilential disease. A serious responsibility rests upon us all to prevent the tragedy of smallpox again becoming endemic in this country."

Diphtheria.—By contrast the figures for diphtheria immunisation showed a gratifying improvement. In the section by Dr. W. H. Bradley and his colleagues, the number of immunisations is shown to have risen from 589,343 in 1947 to 702,744 in 1948; and in addition 490,383 children received a reinforcing injection. The over-all percentage of children immunised increased to 63·5. During the year 3575 cases of diphtheria were notified, with a death-rate of 4·4 per 100 notifications; the figures for 1944 were 23,199, and 4·0.

Scarlet fever.—Notifications of scarlet fever numbered 74,824 and deaths only 37. The death-rate at ages under fifteen was 2 per million, compared with 3 in 1947 and an average annual rate (at ages under fifteen) of 2282 per million in the decade 1861–70.

> "The reduction in the case fatality rate, though in part attributable to the sulphonamides and penicillin, is probably in the main, due to a remarkable natural trend, which has lowered the virulence of the disease. Cyclical trends in the pathogenicity of the *beta* hæmolytic streptococci are well recognised epidemiological features. At present its pathogenicity seems at its lowest ebb. When or whether the picture may change in this country, as it did in the United States of America during 1944, and scarlet fever emerge again as 'the fever,' we do not know."

VENEREAL DISEASE

The steep fall in the clinic figures for early syphilis in 1947 was repeated in 1948, the total number of patients attending for the first time falling from 14,166 in 1947 to 10,637 in 1948, 6603 of these being men and 4034 women. The fall was less pronounced in some large seaports, and clearly there were still large reservoirs of infection in a few great inland cities. The incidence was still more than twice that in 1939.

In his section of the report Dr. G. L. M. McElligott remarks that in view of the great increase in early syphilis in 1946, it was perhaps too much to expect that the fall in first-year congenital infections in 1947 would continue during 1948; and the number of these infants did in fact rise from 343 to 372.

> "A possible explanation of this rise is that the growing practice of routine antenatal blood testing has unearthed more latent infections in pregnant women. Infants born of such mothers, even where the latter have been treated during their pregnancies, often show temporarily positive blood tests for the first few weeks of life. This does not necessarily indicate infection, and it seems likely that an increased proportion of these infants may have been wrongly diagnosed as syphilitic and so included among the first year congenital cases."

The number of cases of late or latent syphilis attending the clinics for the first time rose from 5971 in 1947 to 6492 in 1948.

With regard to gonorrhœa, the clinic figures showed a further fall, male infections declining from 29,647 in 1947 to 25,006 in 1948, and female infections from 7019 to 5306. "The continuing disproportion between the male and female numbers suggests that many women still do not realise they are infected and emphasises the need not only for education and contact tracing, but also for improved methods of cultivating the gonococcus in the laboratory."

> "There is no evidence that ignorance is responsible for many of any male infections. On the other hand the high reputation of penicillin in gonorrhœa is becoming almost too well known and multiple re-infections are often due to a cynical appreciation of its efficacy."

There was some evidence that non-gonococcal urethritis might be becoming more common.

ACUTE RHEUMATISM

Between 1931 and 1935 the number of deaths classified by the Registrar-General as due to rheumatic fever

After a certain amount of repair work had been completed I was able to return to my old job—that of a pharmacist in a London hospital. I was able to see much better, but I found that a one-eyed person has many difficulties to overcome—that of focusing and seeing objects suddenly appear from the blind side being two such difficulties.

I was greatly cheered to find that I could still dispense accurately and from that time onwards I was very keen to get on with the repairs, as I wanted to find a permanent position. Having to go back to hospital so often made it difficult for me to take a job where I was in control. To achieve my present position—that of director of an old-established pharmaceutical business—I had to go through many stages. One of the most exciting moments, from my point of view, was when I first had my artificial eye. This may sound trivial, but it meant that I was, once again, in appearance at any rate, more like my fellows. Now that my face is complete the quick passer-by notices little if anything amiss. The hospital almoner made arrangements for me to visit cosmetic specialists who give free advice on make-up for scarred faces. At the Max Factor Salon I was taught which preparations to use, and my face was made up by them to show me how to apply these products to the best advantage. When they had finished no-one would have known I had a single scar on my face.

The Wolfe graft on my forehead is of much lighter colour than the rest of my face, but my hair always had a natural wave over this side of my forehead and so can be arranged to cover most of the graft.

My artificial eye is made of plastic. The main advantage of this material is that the eye is unbreakable, however roughly treated. The colouring has been so well matched that it is difficult to tell which eye is real: in fact many people have told me how fortunate I was not to lose my eye, and needless to say I did not disillusion them. The socket requires frequent washing, but the eye itself needs little, if any, care. I usually remove it when washing my face, and it is easily rinsed under the tap. Only one chemical has any effect upon it, and that is chloroform; so I have to be rather careful when dispensing, as it would be somewhat disconcerting to feel one's eye gradually dissolving.

Wherever I have worked people have been exceptionally kind and understanding. Only once have I had any unkind words said to me: "Wouldn't you rather have died than go about with a scarred face?" That thought had never entered my head, for there are so many things in life to do.

To me there seems to be a choice for those with facial injuries: either you fight on and face the world or else you go behind doors and lead the life of a recluse. The second choice was never, at any stage, mine—even in the beginning, when I was a mass of bandages—and I would encourage all who have similar injuries to realise how much there is to be gained by leading a normal life.

At first one can never be sure of other people's reaction to a disfigured face, and it hurts one's feelings to see any one shrink. But in time one learns to watch others with detachment. When they realise that one's face is scarred they are apt to become somewhat embarrassed and to wonder whether they should look or not. What does it matter? I have been told by many people who know me that after a time they don't notice any disfigurement at all. In time people will get used to seeing these scarred faces, and there are quite a number about in the world today.

Many times I have thought how lucky I have been compared with some of my fellow citizens; for I have good health, two good arms and legs, and one reasonably efficient eye; and, above all, I have been able to carry on with my career.

Public Health

STATE OF THE PUBLIC HEALTH

RETROSPECT OF 1948

THE ninth year of austerity, 1948, was memorable in many ways, writes Sir Wilson Jameson, chief medical officer to the Ministry of Health; for

> "it was one of struggle against economic adversity in the shadow of international gloom intensified in June by the blockade of Berlin, continual anxiety as to the air-lift to that beleaguered city and growing tension in the Near and Far East. But all these and many other depressing circumstances, the British people took with their usual good-tempered grumbling and that cheerful confidence in ultimate success which has never yet deserted them."

It was a memorable year in other ways as well. On July 5 the National Health Service began its colossal task.

START OF THE HEALTH SERVICE

The start of the service is reviewed in the Ministry's report[1] by Dr. G. E. Godber. The immediate advance was not that all things were at once available, but that there was now a way to secure them in the future. Fortunately, such confusion as arose at the change-over was for the most part in offices rather than in hospital wards, doctors' surgeries, or any of the other places where the patient is served.

In the preparatory phase the greatest pressure fell on the hospital service; and soon after the service started, new factors began to appear. Outpatient attendances began immediately to rise; and the increase was particularly noticeable in gynæcology, radiology, pathology, and ophthalmology. This was not unexpected and "indeed marked only an accentuation of a change already apparent before the appointed day—a change which is steadily increasing the emphasis on hospitals as centres for diagnosis rather than mainly institutions providing beds for the treatment of the sick." There was also an increase in the demand for pathological and radiological investigation for general practitioners.

An appendix shows that between July 5 and Dec. 31, 1948, the 4756 specialists undertaking domiciliary work visited 29,246 patients.

Another early effect was an increased demand for beds for the elderly chronic sick. This was more apparent in London and the South than in the industrial North, and again it was an acceleration of a trend already existing before 1948. During the winter the position, especially in London from January to March, 1949, became extremely difficult, and many old people could not be admitted despite acute illness. The rapid development of home-help services and the extensive use of home nursing did much to relieve hardship, "but there is no doubt that many households and particularly elderly couples living alone need greater relief than such services can give."

With regard to health centres, the only scheme approved for the construction of a new centre was that of the London County Council at Woodberry Down, on which work is now proceeding. No authority has yet put forward a comprehensive programme in a scheme for centres, "and it would be undesirable to confirm such a programme, if one were submitted, in view of our present inexperience in this field."

In some areas the attendances at antenatal clinics fell away as a result of expectant mothers seeking antenatal advice from practitioners booked under the maternity medical service. "It is to be hoped that the since they valuable work of these clinics will not be lost, and classes, in which it spreads very quickly with a high attack-rate, the effect on man-power in industrial areas may be considerable. When the day nurseries close, mothers are kept away from work in the factories, and they may remain absent for several weeks because they hesitate to return the child to the nursery until it is quite well.

---

[1] Report of the Ministry of Health for the Year ended 31st March, 1949, including the report of the chief medical officer on the state of the public health for the year ended Dec. 31, 1948. Cmd. 7910. H.M. Stationery Office. Pp. 373. 7s. 6d.

Notifications.—The incidence is much higher than notifications indicate. Many cases of Sonne dysentery are never seen by doctors. This may be why notifications, when they are made, relate to cases occurring in nurseries and other communities under continuous medical observation. In the absence of fully effective notification, it is difficult to gauge the amount of infection in the ordinary population.

Prevention and Treatment.—Because of its rapid spread, and (in the case of day nurseries) dissemination to the homes from which the children come, early ascertainment and removal of children with gastro-enteritis is imperative, and the general standard of hygiene in the nurseries must be stepped up to the highest possible level. For treatment, there is still some debate about the best drug to use, but sulphadiazine may have advantages.

Smallpox

The following notes describe the origin of the Glasgow outbreak of smallpox:

1. The S.S. *Chitral* left Sydney on Jan. 21 and called at Colombo (Feb. 8), Bombay (Feb. 11), Aden (Feb. 16), and Port Said (Feb. 20–22). She docked at Tilbury at 03·30 hours on March 5. The voyage was without incident in regard to infectious disease. She disembarked 718 passengers including a spare crew of 133: her own crew, numbering 336, remained with her.

2. The spare crew divided and dispersed. On March 5, 52 Indian lascars went to a seamen's hostel in Glasgow, proceeding by coach to Euston and thence by train. Another 61 went by charabanc to South Shields where they immediately joined another ship. On March 7, 20 Goanese went by coach and train to Glasgow, where they immediately joined another ship.

3. On March 7 one of the men in the seamen's hostel at Glasgow sickened. Some hours after admission to Knightswood Infectious Diseases Hospital on March 10, he developed a macular rash which later became vesicular and was diagnosed as varicella by competent opinion. He was discharged on March 23 to the seamen's hostel but was afterwards admitted to the Smallpox Hospital.

4. On March 23 a nurse who had attended the lascar sickened with tonsillitis. On March 25 she developed spots on the face. By the 27th she was diagnosed as having confluent smallpox.

5. Two other nurses and two patients who were ward contacts with the seaman had been removed to the Smallpox Hospital by March 28. Within the next two days the diagnosis of smallpox was confirmed in three of these.

6. Up to March 29 six other persons had been admitted to the Smallpox Hospital for observation because they had been close contacts or for other sufficient reason.

7. Two of the confirmed cases infected in the hospital had travelled during the period of infectivity: contacts have been under surveillance outside Glasgow, particularly at Rosyth and Kirkcaldy.

8. The crew of the *Chitral* and the relief crews were inspected and found to be free from signs of infection. The passengers had dispersed twenty-two days before the possibility of infection on the ship was known, by which time the usual practice of sending warning notices from the port to the medical officers of health for the districts to which passengers had departed would have served no useful purpose. On March 27 steps were taken to contact these passengers by radio and press notices. Three days later there was no report of suspicious illness amongst them.

Scarlet Fever

During the past two months notifications of scarlet fever have approached or exceeded 2000 each week, compared with 1200–1400 a year ago and a median of about 1200 during the same season in the years 1941–49. There also appears to be a much greater prevalence of streptococcal sore throat, with its otic and other suppurative lesions, than has been seen for some years past. In fact in some districts what is colloquially called "flu" appears to be due to a primary *Streptococcus pyogenes* infection.

The medical superintendent of an infectious-diseases hospital in Essex has reported as follows:

> "My impression is that we are now seeing more 'sharp' attacks of scarlet fever; more patients are admitted with complications, and more complications occur within a day or two of admission, which rules out those complications arising out of cross-infection with another strain. Most of the complications are otitis media and adenitis. One child was admitted recently almost moribund and her life was only saved by penicillin. There were no other signs or symptoms to account for the condition and the cerebrospinal fluid was quite normal. Another feature of the recent epidemic is the increased number of adults (that is, over the age of 21 years) admitted with scarlet fever."

Eighty years ago scarlet fever killed more children under 15 years of age than did respiratory tuberculosis at all ages. The death-rate in the decade of 1861–1870 was 2617 per 1,000,000 population. Since 1943 it has fallen to less than 10. The fall in incidence and mortality was an epidemiological phenomenon and not due to chemotherapy. Should highly virulent types of *Streptococcus pyogenes* again emerge, vigorous control measures applied in the localities where they first appear are strongly indicated. Practitioners should call the attention of medical officers of health to a change in virulence when they notify severe cases of scarlet fever.

Statistics for England and Wales

In his latest quarterly return,[1] the Registrar-General reports the following figures for the three months ended Dec. 31, 1949:

Births totalled 169,563, representing a birth-rate of 15·4 per 1000 population. These figures compare with 183,278 births and a rate of 16·6 for the preceding quarter, 179,473 births and a rate of 16·4 for the corresponding quarter of 1948, and an average birth-rate for the fourth quarter of the five years 1943–47 of 17·1.

Stillbirths.—The 3903 stillbirths registered represent 22·5 per 1000 of the total live and still births.

Deaths.—The number registered was 128,349, representing a death-rate of 11·6 per 1000; this compares with 11·5 for the corresponding quarter of 1948, and an average death-rate for the fourth quarter of the five years 1943–47 of 12·0.

Deaths of children under one year numbered 5643, representing an infant-mortality rate, provisionally corrected, of 32 per 1000 related live births; this was the lowest ever recorded for any fourth quarter. The diarrhœa death-rate for children under two years of age was 2·9 per 1000 births, compared with 2·8, 4·0, 2·4, and 2·6 in the four preceding quarters.

Deaths from acute poliomyelitis and polioencephalitis (provisional total excluding non-civilians) numbered 319, compared with 83, 27, 28, and 250 in the four preceding quarters.

Natural Increase.—The births registered exceeded the deaths by 41,214.

The return gives the following figures for the whole year 1949:

Stillbirths.—The rate was 23 per 1000 total live and still births, the lowest ever recorded.

Deaths.—The total death-rate was 11·7 per 1000 total population. This was 0·9 above that for 1948. Infant mortality was 32 per 1000 related live births, and was the lowest ever recorded.

Natural Increase.—Births exceeded deaths by 220,749. The corresponding increase for the preceding year was 307,073, and the average for 1943–47 was 265,728.

Population Estimates.—The estimated population for the year was 43,785,000 (total) and 43,100,000 (civilian)—an increase of 283,000 and 350,000 respectively over the estimate for 1948.

Births.—The provisional birth-rate was 16·7 per 1000 total population (1·2 below that of 1948). The illegitimacy rate was 50 per 1000 live births (18 per 1000 below the average for the preceding five years).

---

[1] The Registrar-General's Quarterly Return for England and Wales: Births, Deaths, and Marriages; Infectious Diseases; Weather; Survey of Sickness; Population Estimates. Quarter ended 31st December, 1949. H.M. Stationery Office. Pp. 33. 1s.

averaged 1210 annually. Thereafter deaths declined more or less steadily to 366 in 1946; but they rose to 400 in 1947 and to 447 in 1948. Yet in the three areas where the disease is notifiable, the incidence during 1948 was less than 1 per 1000 of the child population.

TUBERCULOSIS

The over-all mortality from all forms of tuberculosis reached a new low record—505 per million living. Dr. Norman Smith draws attention to the disturbing increase in the proportion of deaths from tuberculosis of patients not notified before death. Whereas before the late war these were about 1 in 8 of the deaths, they are now almost 1 in 6.

At June 30, 1948, there were 29,420 tuberculous patients receiving institutional treatment—an increase of 7% over the 1947 figure. The increase in the waiting-list, however, was about 12% Some 966,000 civilians were examined by mass miniature radiography, bringing the total thus examined since October, 1943, to 2,985,607, of whom more than 94% were found at the time of examination to have no abnormal chest condition. Previously unsuspected active tuberculosis of the lungs was found in less than 4 per 1000 persons examined.

CONSERVING HOSPITAL BEDS

In the section on hospitals Dr. Charles Maitland draws attention to various means of saving acute hospital beds, as by the greater use of outpatient departments for diagnosis and treatment, or by providing simple hostel accommodation. The time of fully trained nurses can be saved by planning the wards to make observation of patients and their service easier; by reducing as far as possible time-consuming routine nursing procedures such as bed-panning; by encouraging patients to help themselves; and by employing ward "helps," ward orderlies, and other sorts of hospital personnel who, if of suitable temperament, can competently carry out many nursing services customarily reserved for fully trained nurses.

An appendix gives the total number of beds under regional boards and boards of governors as 504,209 (non-teaching 477,729, teaching 26,480), of which 64,695 were temporarily unavailable on Dec. 31, 1948. The number of maternity beds available on that date was 18,786.

"SUFFOCATION" IN INFANCY

The section on child-care refers to the increase in deaths of infants under one year of age ascribed to accidental mechanical suffocation.

Through the maternity and child-welfare group of the Society of Medical Officers of Health, information was collected on 94 cases. In 49 of these 94 deaths cases, death was ascribed to inhalation of stomach contents, in 42 cases to smothering, and in only 3 to disease—i.e., tracheobronchitis or pneumonia. In 68% of the cases the maternal care was regarded as good or satisfactory. In only 9 cases was it recorded that the mother went out to work; and in all but 1 of these 9 the deaths occurred at night or on a Sunday, when the infant was in its mother's care. 73% of the infants were legitimate, so that illegitimacy with its risk of poor mothering could not be regarded as a strong factor. The available information did not suggest that wrong feeding methods or maternal carelessness or preoccupation was a preponderating factor.

Despite accounts indicating that many deaths which clinically might be attributed to suffocation have been traced to infection or other abnormality, "it is still common for no autopsy to be made on a case of alleged mechanical suffocation, reliance apparently being placed entirely on circumstantial evidence at the inquest." Thus, in this series of 94 cases there were 42 where death was recorded as due to smothering in the infant's cot or in its parents' bed, but autopsies had been made in only 24 of these; and "it appears still more uncommon for any microscopic examination to be made, the finding of inhaled stomach contents or the signs of asphyxia being accepted as the cause of death rather than as possibly merely terminal events . . . the coöperation of coroners and pathologists is needed to elucidate the causes of the increased incidence of these deaths."

Influenza

A previous note (March 18, p. 520) reported the incidence of influenza and pneumonia up to Feb. 25. In the following tables the figures for the four weeks ending March 18 have been added. Although during this period, there has been a steady increase in "influenza" deaths, the aggregate of 429 deaths in the 126 great towns compares with 1246 during the corresponding four weeks in 1949. The weekly figures may continue to rise slightly for a week or two, but it would be surprising if epidemic proportions were reached.

PNEUMONIA AND INFLUENZA IN GREAT TOWNS

Influenza										
Deaths ..	47	39	47	61	80	76	78	76	108	167

* Including influenzal pneumonia.

TOTALS FROM FIRST WEEK OF 1950 IN GREAT TOWNS COMPARED WITH CORRESPONDING PERIOD OF PRECEDING TWO YEARS

	1948	*1949*	*1950*
Pneumonia			
Cases ..	5123 ..	7797 ..	6328
Deaths ..	3064 ..	4453 ..	3547
Influenza			
Deaths ..	242 ..	1677 ..	831

In the Northern Regions a peak of 25 deaths occurred in the week ended Feb. 11, since when deaths have fallen to zero. There appears to have been a trek from north to south, and at the end of March the main incidence was in the north-western and Midland regions. Further small rises in London and the south-west are to be expected. Throughout the year more than two-thirds of the deaths have been in persons over 55 years of age.

Dysentery

Incidence in Recent Years.—The number of notifications of dysentery in England and Wales rose to a peak in April, 1945, and remained excessive for nearly a year. In the spring of 1946 it began to fall rapidly to a low level, the lowest point being attained in June, 1947. Thereafter there was a moderate rise until in 1948 it was a third of the 1945 figure. In 1949 it was slightly lower than in 1948, but it increased in the last quarter.

Incidence in 1950.—This increase gained momentum. The averages of weekly notifications in January, February, and March were:

	Annual mean of 9 years *1941–49*	*1950*	
January ..	171	170	
February ..	195	333	
March ..	208	321	(up to March 11)

These figures suggest that a situation similar to that of 1945 may be developing.

Bacteriology.—The dysentery now gaining prevalence in the country is almost exclusively of the Sonne type.

Geographical Distribution.—So far this year the disease has been almost confined to the northern half of England, the highest incidence being in the West Riding of Yorkshire with a heavy concentration in Sheffield. In recent weeks over half the notified cases have been contributed by seven towns—Manchester, St. Helens, Lancaster, Newcastle, Nottingham, Leeds, and Sheffield.

Comparison with 1945.—Up to March 18 notifications this year totalled 3066, whereas in 1945 there were 5163 in the first quarter of the year. Thus this year's epidemic is on a smaller scale; but a spread to the south might cause a very considerable increase.

Comment.—Though in this country Sonne dysentery cannot be regarded, clinically, as a serious disease, it occasionally kills in the extremes of life. Because the attack falls mainly on young children and the disease has a special affinity for day nurseries and nursery schools tickets weren't used, my dear chap," I replied, "the matrons would be afraid of the generous theatrical folk taking offence and cutting off supplies. And they like their nurses to have little outings." By now he was in his outdoor clothes. "Well, all the same I wish someone would tell them not to come unless they really want to," he said. "Can't you do something about it?" "I'll do what little I can," I promised; and I'm doing it now.

* * *

Reinforced concrete in the construction of modern buildings makes, we are told, for sturdiness and durability. But oh! the trouble when something goes wrong with the works, especially in hospital. Some undiagnosed deep-seated mischief has tried to rear its ugly head under the floor in the kitchen of the private ward, and a pneumatic drill has been called in to unmask it. The noise and vibration are bad enough on the ward involved, but my office immediately below acts as a resonating chamber and is completely uninhabitable. No more postprandial snoozes or smokes; never was the stimulus to go into the ward (preferably to the furthest corner) greater. This must be a speeded-up version of the ancient Chinese torture where the victim lies with his forehead under slowly dripping water. Returning after lunch to find a young and well-controlled epileptic outpatient sitting in anguish, I pondered on the possibility of this fiendish instrument's having similar properties to the stroboscope, but—another blow to clinical research—my own powers of endurance failed first and we adjourned to another room. Sister has been rendered speechless (a state of affairs never hitherto accomplished by any human agency), and contents herself with helpless gestures; but one new patient, admitted for a craniotomy, said to me cheerfully: "Well, Doc., I hear you've got your instruments handy." Poor chap. He doesn't know how close he was to the mark.

* * *

Baby-sitting—after bed-time—is one of my accomplishments; in England I can do it standing on my head. A night or two of the job in Denmark however has taught me a thing or two, and there are still a few points in the contracts which, I think, need clarification.

To begin with, there is some confusion as to just which babies you are minding. In a city your particular family is certain to live in a flat, and the flat will have four contiguous flats, each containing at least one baby not to mention radios, pianos, and female relatives practising soprano arias. The Danes are a cheerful and music-loving people and the evening is the time they let themselves go. The walls, floors, and ceilings of these enormous apartment buildings seem to be made of peculiarly conductive materials, so an infant with hiccups three flats along can send the really conscientious sitter-in on a stealthy tour of the home territory, only to find two sprawling young Nordics, wholly uncovered, wholly at ease, sleeping peacefully.

Again, there may be a little difficulty with language. The reassuring tucking-in after a bathroom excursion or the frank cuddle of the day-time-haughty six-year-old comes easily enough in any language; but what of imperative demands in mime leading to liftings-up and consequent tit-bit hunting in larders? My charge last night insisted on rising at intervals and demanding cotton-wool (which for all I knew was sacrosanct in its bag behind the bathroom door), which with great deliberation she rolled into pledgets and wedged into either ear. She did not appear to be in any pain, so I can only assume the act symbolic and possibly of international significance. This particular infant perturbed her parents by backsliding into baby talk in my presence; it took her mother several days to find out that this was done expressly for my benefit, because I "couldn't talk right."

Telephones are best left to ring unanswered, I find. When one cannot speak one word of the caller's language awful confusion can arise. In any further contracts I shall insist that the times of the B.B.C. news bulletins are observed as a cease-fire. It is only fair that a British sitter-in in Copenhagen should get a little reassurance too.

Letters to the Editor

WAR

SIR,—Dr. Ranyard West's statement, in his letter of March 25, that when we look in the mirror we see a war-monger, is based on profound insight.

It is interesting that the point of view which he puts forward, and that which I outlined in my previous letter (March 18), find perhaps their only modern synthesis not in a psychiatric study but in Camus's novel *The Plague*. The "plague" which Camus describes is, in essence, the irresponsible acceptance of aggressive acts as short-term answers to social problems (more precisely, in Camus's own words, it is "murder," in which he includes judicial execution, war, assassination, and many other forms of rationalised aggressive behaviour): "we are all infected with the plague, and the least we can do is to avoid coughing it in other people's faces"; and again "In this world there are pestilences and there are victims, and it is up to us not to ally ourselves with the pestilences."

The element which I find implicitly in Camus, and far more explicitly in the work of writers such as Reiwald, is the realisation that the conception of law and order which is traditional in Western European thought is itself heavily infected with conscious and unconscious aggression. Reiwald [1] points to the strikingly paranoid attitude of institutional government toward crime—society is always threatened by "armies of criminals" which have no statistical reality—and to the fundamentally aggressive and emotive basis of the idea that law and order depend upon coercion. There is a basic identity between this craving for "defence" and the "adequate defensive forces" which compete to generate an arms race. Our use of the term "public enemy" indicates something of this spill-over into our attitude towards delinquents of the diction and ideology of war. Dr. West himself has given support to this thesis in his explicit suggestion [2] that international order depends upon overwhelming force in the hands of a world authority.

The point I am making is that war is an extension not of anarchy or group hostility but of the processes which are inherent in the traditional view of government. It is precisely this tradition which is being challenged in penology, and the challenge presented by the extension of psychology to political institutions is the same. In the light of this, one may reasonably doubt whether governments do, as Dr. West suggests, confine their delinquencies to the field which lies outside domestic law-giving. If, then, the technique of war is in essence an extension of the technique of government, it might be better to rely upon a mobilisation of world opinion to resist national authority, rather than a mobilisation of authority itself, together with the legacy of psychopathic tradition which such authority already exhibits.

London, S.E.23. ALEX COMFORT.

RESEARCH ON ARTHRITIS TREATMENT

SIR,—We should like to draw your attention to the results obtained with the new preparation 'Cafestol,' one of the group of substances isolated from the unsaponifiable fraction of the seed of *Coffea arabica L.*,[3] which has now been introduced in therapeutics and has the same indications as 'Cortisone.' In our institute a first group of 16 patients treated with this substance were suffering from polyarthritis due to rheumatic fever (4), rheumatoid arthritis (8), degenerative arthritis of spine (3), and ankylosing spondylitis (1).

The results have on the whole been satisfactory. They were more evident in the inflammatory disorders, especially the acute ones; the benefit was less evident

Effective Reproduction-rate.—The effective reproduction-rate corresponding to the births in 1949, allowing for continuing improvement in survivorship conditions, is provisionally assessed at 1·02, indicating that the births were 2% in excess of those required by a par replacement standard.

A report on the survey of sickness in the September quarter, 1949, is also included in the return.

Smallpox at Sea

Smallpox on Merchant Ships, issued by the Ministry of Transport (notice no. M342), outlines for ships' surgeons the main clinical features of smallpox, together with notes on precautions and treatment.

Medicine and the Law

Mistake in Morphine Injection

At a recent inquest upon the death in hospital of a patient aged 72 there was evidence that he died less than four hours after having been given a half-grain injection of morphine and that the injection had been intended for another patient whose name began with the same capital letter and was perhaps otherwise slightly similar. The assistant nurse who administered the drug admitted that she had not checked the prescription with the case-sheet. The coroner expressed the opinion that such checking would have prevented the mistake. The pathologist who carried out the post-mortem examination stated that death was due to heart-failure and chronic bronchitis and was accelerated by the morphine. A verdict of death by misadventure was recorded.

Hospital practice has hitherto required a qualified nurse or sister to "check" the dose—to see that the right quantity of the right drug has been drawn into the syringe. Does the evidence at the recent inquest mean that it is now left to an unqualified nurse to administer the actual injection?

Parliament

QUESTION TIME

Surgeons in Malaya and Singapore

Mr. A. J. IRVINE asked the Secretary of State for War what was the number of British Army surgeons now serving in Malaya and Singapore; and whether he was satisfied that such number was sufficient.—Mr. JOHN STRACHEY replied: There are 7 British Army surgeons serving in Malaya and Singapore. They are available to fly to any locality where their services may be needed. This is an addition of 3 Royal Army Medical Corps surgeons to the numbers previously serving in Malaya and Singapore. I am keeping the requirement under careful review. There are, in addition, 16 European civilian surgeons in Malaya and Singapore who can be, and are, called on should Army surgeons not be immediately available.

Tuberculosis in Scotland

Replying to a question, Mr. HECTOR MCNEIL stated that notifications of respiratory tuberculosis in Scotland in 1939 numbered 4657; in 1945, 7316; in 1947, 7984; and in 1948, 8204. The provisional figure for 1949 was 8427.

Our Calorie Intake

Dr. BARNETT STROSS asked the Minister of Food whether he was aware that the total calorie intake pre-war from grain and potatoes was 34% and in 1946 was 42%; and whether he would now give the figures for 1947, 1948, and 1949.—Mr. MAURICE WEBB replied: The corresponding figures for 1947, 1948, and 1949 are 43%, 43%, and 40%. Dr. STROSS: Is the Minister aware that the last figure shows that we are undoubtedly improving the national dietary?

Mr. HENRY STRAUSS: Has the right hon. gentleman ever invited a friend to a calorie intake?

The Minister of Health has appointed Mr. W. D. Griffiths, M.P. for the Exchange division of Manchester, to be his parliamentary private secretary.

In England Now

A Running Commentary by Peripatetic Correspondents

OUR life has lately been lightened by the arrival of a displaced person—a young woman of 30 who is a Rumanian-born German. She views life in England with a mixture of suspicion, criticism, and admiration, and she is timid of venturing outside the house alone or encountering strangers. Not long ago, just before restraints on the sale of eggs were removed, I wandered out one afternoon to ask for half a dozen eggs from the smallholding nearby. On the way I met the village policeman who always likes a chat; he has a round and guileless face which invites confidences, and a broad Devon accent. Presently I swung my basket and said I must be going along, as I wanted some eggs if Mrs. Smith were at home. "She's at home," said the constable encouragingly, "'cos the man from the packing station's there. I saw his van as I passed." "Then it's no use my going," I said. "All the eggs will be gone. I'll go tomorrow." "You could go and see," said the policeman. "Look, I can see from here, he's just leaving and he'll be gone in a minute." He was clearly anxious I should not be disappointed. But I returned home, knowing there would be no eggs that day, and over tea I recounted my meeting. Then a thought struck me. "There was I," I exclaimed, "doing a little bit of black-marketing and telling the policeman all about it. *It never occurred to me not to.*" I happened to glance at Elsa and saw her face a study of horror. "Told the police!" she murmured. My husband glanced at her and began to speculate aloud on the probable length of my sentence. Presently she realised that he was joking and she relaxed, but remained puzzled. These extraordinary English, who expect their police to behave like reasonable human beings!

* * *

With a deep sigh he smeared removing-cream over his face and wiped the grease-paint off with a towel. "I'm sorry you struck such a poor evening," he said. "It was all right," I replied, "but what on earth was wrong with the audience? I've never been in such an apathetic crowd." "Nurses;" he sighed again, "from Wednesdays onward for the rest of the week we are booked out. For months ahead. But Mondays and Tuesdays are thin: I don't know why. Today the management panicked and papered the house with hospital nurses. Tell me, why are they so damnably unresponsive? Is it because they don't value anything they don't have to pay for?" I felt it was up to me to stand up for the girls. "That has got something to do with it, without any doubt," I replied. "I remember when I was handed complimentary tickets as a houseman. I guessed they couldn't be got rid of in any other way, and my approach to the show tended to be rather. . . ." I hesitated. "Hypercritical?" he suggested. "Worse than that: a sort of 'Damn-you-you-dragged-me-here-now-amuse-me' attitude. Why, I remember once walking out of a revue before the end when I hadn't paid for it." "But you weren't *forced* to go in the first place, were you?" he asked. "You're not *forced* to take the pamphlet a man in the street hands you," I said, "but you do take it and shove it in your pocket, and perhaps you glance at it before you throw it away. But you don't memorise it, or even file it away. What I mean is that my attitude was very different when I'd plonked down five-and-nine for an upper circle or stood my two hours for the pit: then I was bent on enjoying every moment of the show." I felt I was talking too much but as he was merely goggling at me and putting on his tie I swept on. "Another thing: you get a random selection by suddenly enlisting nurses who happen to be having their half-day." "Half-day?" he asked. "In a hospital most of the nurses are on duty till nine o'clock," I explained. "There is only a handful off duty when free tickets roll along. And a good proportion of these wouldn't choose a philosophic comedy for their evening out. Their cup of tea may be musical comedy, ballet, or old Vickery. But they have to take whatever comes their way." "Well," he said, "I wish they wouldn't. I'd rather they stayed away." "But if the provided precautions have been taken to exclude extraneous sources of blood, an attempt must always be made *to trace the cause of the bleeding*.

Interpreted thus critically, these tests can be indeed valuable, as you suggest. If they were widely applied in general practice, alimentary disease would be more rapidly detected at a stage when treatment can be successfully instituted.

Edinburgh. S. LIPETZ.

DIAGNOSTIC CHEST FLUOROSCOPY

SIR,—In advocating the use of fluoroscopy rather than radiography in the search for pulmonary tuberculosis, Dr. Hall and Dr. Tattersall (March 18) are taking a retrograde step. No-one can deny that an X-ray film is more reliable than screening in the detection of a small pulmonary lesion, no matter how much skill and visual purple the fluoroscopist may possess. In addition, the X-ray film provides a permanent record which may be of very great value in the future management of the patient.

Why then should we use fluoroscopy in diagnosis when a better method is available? Dr. Hall and Dr. Tattersall give two reasons—ease and speed of examination, and cheapness. In your annotation on their article you quote an impressive body of evidence, covering some thousands of cases, to show that 13–35% of clinically significant lesions are missed when fluoroscopy alone is employed. I submit that, in the campaign against tuberculosis, we cannot afford such a sacrifice of reliability for the sake of speed and cheapness.

The pioneer work of Toussaint and Pritchard in London has shown the value of coöperation between the chest clinic and the local practitioners when diagnostic radiography is available. The time has come for all tuberculosis workers to insist that every chest clinic must be provided with an X-ray plant and an adequate staff, so that a film may be taken of every patient who comes up for diagnosis. A screening apparatus is also essential in any clinic where pneumothorax refills are undertaken, but its use should be restricted to this work and to the study of movement.

Surely our task is to press for an efficient service and not, as your annotation suggests, " to think of ways of lightening the load." A revival of the obsolescent practice of diagnostic fluoroscopy would be particularly unfortunate at the present time, since it might persuade those responsible for providing the equipment of chest clinics that a relatively inexpensive fluoroscope can be substituted for an X-ray plant.

Brompton Hospital Sanatorium,
Frimley, Aldershot, Hants. A. F. FOSTER-CARTER.

SIR,—Dr. Hall and Dr. Tattersall are to be congratulated on their excellent exposition of the technique of chest fluoroscopy. But surely they go too far in suggesting that fluoroscopy should supplant, rather than supplement, radiography in diagnostic chest clinics. Practitioners referring cases to these clinics are entitled to receive a first-rate opinion based upon all relevant clinical, pathological, and radiological investigations. As far as radiology is concerned, the matter can be summarised by the following equations:

Radiography+fluoroscopy = Best
Radiography alone = Next best
Photofluoroscopy alone or Fluoroscopy alone } = Not good enough.

For years, chest physicians have been urging practitioners to send up cases for examination and chest radiography on the slightest pretext. Now that this advice is meeting with an ever-growing response, we should not resort to second-rate methods just because the volume of work is growing faster than the present provision of facilities. If it is thought that expenditure on X-ray film is likely to become too great for the country to afford, it would, in my personal view, be cheaper in the long run to spend money on research into electronic methods of enhancing the brilliance of the X-ray screen image. If this could be done, there would be little need for radiography. The money spent in the eventual treatment of even a few minimal cases " missed " by chest fluoroscopy would take us far towards achieving this goal!

Leeds. J. ASPIN.

SIR,—Dr. Hall and Dr. Tattersall are to be congratulated on their most timely article of March 18, which amplifies Dr. Tattersall's original account of the use of this method in the chest clinic. There is, unfortunately, still considerable opposition to the use of this diagnostic technique, on the grounds that fluoroscopy does not give as accurate results as does a full-size radiograph or even mass miniature radiography, and that both operator and patient are exposed to radiation risk.

Having screened for diagnostic purposes more than 2900 patients during the last eleven months, I feel that, provided a careful technique is strictly adhered to, the results obtained are at least as good as those of miniature fluorophotography. Where no pulmograph is available, chest physicians should be encouraged to make greater use of fluoroscopy in the interests both of early diagnosis and of economy in time and materials.

In our experience, several minimal apical lesions found on fluoroscopy could subsequently be identified either with difficulty or not at all on the conventional postero-anterior film, though these lesions might be demonstrable by special techniques such as the apical lordotic film. So far no patient found negative by us on fluoroscopy has subsequently been notified as tuberculous, so that it seems that no lesion of any size has been missed by this method. As Dr. Hall and Dr. Tattersall emphasise, fluoroscopy has the advantage of giving a dynamic, three-dimensional view of the lung fields, and of rendering visible obscure portions such as the posterior costophrenic sinuses, the upper and posterior mediastinum, the retrocardiac area, and the regions covered by the conjunction of first rib and clavicle.

Although we are now screening at the rate of 100 patients a week, investigation by the National Physical Laboratory showed that neither physician nor radiographer was receiving as much as 0·05 röntgen of radiation in one week. The British X-ray and Radium Protection Committee recommend that the dose should not exceed 0·5 rontgen per week. There is therefore no evidence that the method exposes the operator to any considerable risk. 3000 screenings in a year represent a notable saving both in the cost of materials and storage space and in the time of patients and staff. The ease with which a fluorography report can be obtained has encouraged practitioners to refer patients with minimal symptoms, and often only because of a bad family history or of a history of contact at work. In this way a higher proportion of early cases has been seen during the past year than previously. It is frequently objected that fluoroscopy leaves no permanent record beyond the operator's report. This is equally true of any other clinical examination except where results can be expressed in figures or by a mechanical tracing (e.g., weight, blood-count, photograph, or electrocardiogram). In my view this objection is more than counterbalanced by the obvious economic advantages.

The merits of diagnostic fluoroscopy must not, however, blind us to its limitations. It is an incomplete method of examination, and a negative report does not exonerate the general practitioner from examining his patient and, if necessary, referring him for further advice. It is noteworthy that all too often patients are referred in the degenerative forms. In the cases of polyarthritis due to rheumatic fever, pain rapidly diminished and there was progressive reduction in the articular swelling, the temperature, and the sedimentation-rate.

This substance has also been tested on 5 cases of blood disease—2 of acute leukæmia, 1 of chronic myeloid leukæmia, and 2 of Hodgkin's disease. In the cases of acute leukæmia it had virtually no effect. In the case of chronic leukæmia, however, the result was encouraging: the size of the spleen diminished and peripheral leucocytes became fewer. The results were also hopeful in the two cases of Hodgkin's disease, where the affected lymph-glands became progressively smaller.

The doses used varied from a maximum of 400 mg. (loading dose) to a minimum of 100 mg. (maintenance dose). The preparations used were always well tolerated; there was no restlessness, insomnia, or change in the blood-pressure or pulse-rate. No appreciable effect on carbohydrate and mineral metabolism has been observed.

In the cases of arthropathy the circulating leucocytes gradually grew fewer and relative lymphocytosis and eosinophilia was observed.[4][5]

Thus for the first time a substance of vegetable origin to which a formula of steroid nature has been ascribed, has been found clinically to have the same applications as the most potent steroids of animal origin. This discovery reveals a new field for biochemical research.

Institute of Pathology,
University of Pavia.

GIORGIO FERRARI
ANNIBALE ALLEGRI.

BLOOD IN THE STOOLS

SIR,—Your annotation of March 18 touches an aspect of diagnosis in which the general practitioner can play an important part. It is to his own doctor that a patient first goes, and it should be almost axiomatic that when symptoms of alimentary upset do not clear up in a few days, or where the cause of an illness is obscure, particularly in patients past middle-age, the stool should be examined for occult blood. It is true, as you say, that tests for occult blood have in some quarters fallen into disrepute. That is not because most gastro-enterologists consider them unreliable, but because of the short cut to diagnosis by X-ray examination, and because of uncertainty about interpretation of positive findings.

The test now pretty generally used in clinical laboratories is the benzidine test: it is perhaps the most sensitive of all, giving a positive result in blood diluted to 1 in 250,000 parts of water. For routine use in general practice, however, there are obvious objections to a test which gives positive results with gum-bleeding, and after the eating of meat in moderate amounts. It was to overcome such objections that Gregersen[6] introduced his slide test, universally known as the Gregersen slide test (G.S.T.). By reducing the sensitivity of the benzidine test to one-third, he produced what is now regarded as one of the most reliable tests for everyday clinical use. He discarded the unstable hydrogen peroxide and substituted the more stable barium peroxide in a concentration of 4%. Using a 50% acetic-acid solution, the benzidine concentration is kept at 0·5%. The practical application of the test is thus standardised, and leaves no room for error.

A powder containing 0·025 g. of benzidine and 0·2 g. of barium peroxide is dissolved in 5 ml. of 50% acetic acid. A portion of fæces, the size of a split pea, taken if possible from the interior of the specimen, is smeared on a clean glass slide; a few drops of the reagent are added. In the presence of blood, a blue colour, varying in intensity with the amount of blood present, develops in less than a minute. Because different makes of reagent give varying results, it is advisable always to use the same make.

The Gregersen slide test is fully described by Harrison[7] and by Hutchison and Hunter,[8] and is widely used on the Continent and in America. Boas favoured it, and Ogilvie,[9] concluded that a blue or a blue-green colour, appearing within 30 seconds, is positive proof of the presence of occult blood, irrespective of the patient's diet, with the obvious exception of black pudding, liver, bone-marrow, and other foods with a high concentration of blood pigment.

Unlike the guaiac test favoured by Hoerr, the Gregersen slide test gives no false-positive results with iron, and it requires only two reagents instead of three. Further, the reagents are stable over a period of at least six months, whereas the guaiac solution has to be renewed after a month. It is surprising, therefore, to read in the report of a discussion following their paper, that Hoerr and his colleagues had no experience of this widely used test which has so well-established a place in the textbooks.

I have used the Gregersen slide test in general practice for the past twenty years and have described[10] a series of 123 alimentary cases (including 102 cases of peptic ulcer) in which both X-ray and G.S.T. findings are available.

The G.S.T. findings were compared with the X-ray and clinical findings, including in some cases confirmation after operation. Both the G.S.T. and X-ray findings were positive in 69 (68%) of 102 ulcer cases, and in 18 (86%) of 21 other conditions. The G.S.T. was positive and the X-ray findings negative, but clinical observations and subsequent history confirmed the positive diagnosis, in 19 of the 102 ulcer cases and 3 of the 21 other cases. The G.S.T. was negative, and positive X-ray findings confirmed the clinical findings, in 14 of the 102 ulcer cases, but in none of the 21 other cases. Thus there were 22 cases which might have been missed if the G.S.T. had not been used, and 14 cases in which the G.S.T. did not support the diagnosis.

In more than two-thirds of all cases both the G.S.T. and the X-ray findings were positive. Of these 87 cases, all but 22 were first diagnosed with the G.S.T. Where the two tests gave differing results, the G.S.T. was right rather more often than the X-ray findings (22 cases and 14 cases respectively). Of the 19 ulcer cases with initial negative X-ray findings, 3, radiographed again after an interval because of a persistently positive G.S.T., gave a positive result; and 2 cases, one of neoplasm and the other of diverticulitis, both of them with initial negative X-ray findings and re-examined for the same reason, subsequently gave positive X-ray findings. These 5 cases are perhaps among the most significant in the series.

As regards ulcer only, both tests agreed in two-thirds of the cases; radiography failed in slightly under 1 case out of 5, and the G.S.T. in slightly less than 1 out of every 7 cases. For the other diagnoses the numbers are too small to give more than a strong indication: 11 cases of neoplasm; 5 which exhibited diverticulosis radiologically and had a positive G.S.T. (presumably cases of diverticulitis); and 1 case each of ulcerative colitis, regional ileitis, torsion of the cæcum, spastic colon, and pernicious anæmia.

For the general practitioner the G.S.T. can be a valuable aid to early diagnosis and treatment of ulcer. By its use he can sift and control his dyspepsias with more assurance and a better knowledge of the underlying pathology. Often it may enable him to decide more quickly which case requires the more expensive and time-consuming forms of investigation. By taking appropriate measures until all occult blood has disappeared from the fæces, it may enable him to avert the more serious complications of hæmorrhage and perforation. As the minimal amount of blood required to give a positive result varies from one person to another, a negative finding must not be considered conclusive and should always be judged in relation to the clinical picture. A positive result is always significant; and, therapeutically, and with the present-day need for economy it would seem that this secret process is a luxury the taxpayer could well forgo.

It is high time someone blew up this myth about manufacturers bearing the cost of research and evolution of formulæ. They do not. The consumers do. And the manner in which the consumers pay is very clearly shown in the figures given above.

In conclusion, may I, as a pharmacist, suggest that if the doctor wishes to give his patients the best medicines available but without extravagant cost, he should turn a deaf ear to the eloquence of the manufacturer's representative and ask the nearest chemist. He knows.

COBALT AND RED CELLS

SIR,—Having read your leading article[1] under this heading, may I draw your attention to the fact that we did not recommend cobaltous chloride by mouth in doses as high as 500 mg. Only in the first experiments, on ourselves, did we use such a dose, and we found it much too high. For treatment, as we stated,[2] we used intravenous injections.

This misunderstanding may be due to the fact that Kark, and also Castle, misunderstood our doses and erroneously cited in their papers these high doses. 500 mg. led to acute intoxication, whereas, as Kark observed, doses of 20–60 mg. are tolerated without trouble. In our clinic, cobalt therapy has been extensively used, with excellent results, since 1947. Tests in other clinics have proved that these results could easily be reproduced. Even Castle could not deny success in cases of anæmia—for example, Cooley's anæmia—where treatment had previously been unsuccessful.

You are right in supposing that cobalt is an unphysiological stimulus to erythropoiesis. I dare say that cobalt deficiency does not exist in man. Nevertheless cobalt seems to be one of the strongest stimuli to hæmopoiesis: and in certain cases one should use it—not as a panacea but only on special indications. Regarding the mechanism, may I mention that cobalt does not necessarily lead to erythropoiesis through a sort of hypoxæmia of the bone-marrow. As I tried to prove in my monograph,[3] it seems to act through blockade of hydrogen-transferring redox systems which is compensated by polyglobuly.

Freiburg, Germany.

GENERAL PRACTICE TODAY

SIR,—I have read the Collings report with interest. From my own experience I do not consider Dr. Collings's choice of practices a fair and representative sample. In the field survey which I undertook in 1947 and 1948 on behalf of the British Medical Association I visited nearly three times as many general practices as Dr. Collings, and included the industrial, rural, and agricultural areas, the great cities, their suburban and dormitory areas, the seaports, the holiday resorts, and the mining areas. The data which I obtained built up the narrative of general practice which is given in the British Medical Association's report on health centres, published in July, 1948.

It would be idle to pretend that the conditions that Dr. Collings describes in the industrial areas do not exist, but on the other hand they are not indicative of the general standard of general practice in this country. The encroachment of the specialist into general practice and the substitution of general practice by local-authority service has, as Dr. Collings points out, produced a state of affairs which is reducing the competence of the general practitioner to whom the patient is a member of the family and not just a case. This point was appreciated by the Health Centre Committee of the British Medical Association and it is unfortunate that Dr. Collings did not at least refer to the recommendations made in planning for the future by that committee.

Much of Dr. Collings's first recommendation, that an attempt must be made to define the future province and function of general practice, has, in fact, been carried out. Admittedly this was not carried out by general practitioners alone, but should general practitioners alone undertake this task? In the past general practice has been affected adversely by the mass production by the colleges and universities of diplomas in subjects which rightly remain within the general-practice field, and again, by the Ministry of Health in legislating for a National Health Service which has produced an isolated general-practitioner service, divorced from the specialist and preventive-medicine services. Can the future functions of general practice be defined without the coöperation of representatives of the other services?

I cannot agree with Dr. Collings's second recommendation that basic group-practice units should be formed as soon as possible. I cannot believe that group practice would be either applicable or economical in the rural and sparsely populated areas of England. Further, I think we should be realistic and face the fact that the development of group practice is unlikely in large cities where there are teaching hospitals and large numbers of practitioners in exclusive consultant and specialist practice. A more practicable and possible solution would be the grouping of general practitioners into "family practice units" as envisaged in the British Medical Association's health-centre report.

The need for early experimentation in the setting up of these units is urgent. If Dr. Collings's report—misleading though it be—produces this, it will have succeeded where more considered ones have failed.

Durley, near Southampton. J. REVANS.

SIR,—Having spent part of my weekend reading through Dr. Collings's indictment of general practice and general practitioners, I can only suggest, to start with, that to equate this very one-sided account of medical activities in Great Britain today, Dr. Collings should also "sit in on" consultants at their outpatient clinics. It is conceivable that they also might hear something to their disadvantage from the fault-finding Dr. Collings.

But Dr. Collings suffers from a not uncommon kind of snobbery in which everything done in a hospital takes on some kind of sacrosanct appearance. An examination done in hospital has some mystical properties which it does not possess elsewhere, even if equally well done. An instrument boiled in a steriliser (electric, of course) acquires aseptic qualities quite other than those possessed if boiled in a pan over a gas-ring in a G.P.'s surgery.

He forgets all the ancillaries which hover around the hospital doctor—the houseman, nurses, clerks, almoners—and he makes no attempt to assess the many stresses and strains suffered by the G.P. in his rôle of head cook and bottle-washer, and scribe as well, as he sees these hordes of patients which pass in front of him ("200 out in the garden" in one case). He fails, too, to see the "state of society" in this country today as portrayed by these queues outside a doctor's surgery, the sheer and shameless mendicancy of much of it. But Dr. Collings, the perfectionist, is too much taken up in imagination with himself conducting the practices which he was "sitting in on" (to use his quaint phrase) to see anything else much. His "absolute" standard is presumably his own self doing things as we would all like them done.

to the clinic for what is really a primary examination, rather than for a consultant opinion. A negative report, as with mass radiography, may lead to a false sense of security, for the patient may have been examined before any radiological abnormality was demonstrable.

Diagnostic fluoroscopy is an arduous procedure for the operator, and the number of patients examined at any one session should not exceed 20, because of the risk of vigilance becoming impaired by fatigue. As Dr. Hall and Dr. Tattersall say, certain lesions are difficult to see on the X-ray screen—in particular fine miliary shadows. For that reason I would recommend that the lowest possible kilovoltage and milliamperage to secure adequate illumination should be used when examining the lung fields; otherwise the picture will be too " hard " and fine structure will be " burnt out." With the Phillips D.X.4 set and Phillips Levy-West screen, our practice has been to use on the average patient 3·5–4 mA and 60–70 kV, increasing to 5 and 75 respectively when examining the heart and mediastinum. Fat patients are unsuitable for fluoroscopy, and I have also found it unsatisfactory in the examination of children for hilar enlargement.

So long as these limitations are kept constantly in mind, I think the widespread adoption of diagnostic chest fluoroscopy is to be recommended where mass miniature radiography is not available.

DIET IN HYPERTENSION

SIR,—I have read with interest your leading article of March 25.

There is no doubt at all that a low-protein intake causes a definite reduction in arterial pressure. The cumulative effect of such a reduction over many years must be considerable. We have established that in essential hypertony there is a tendency to nitrogen retention (protein), and on this account alone it is vital that the protein intake should be restricted.[1] Also we found that a high-fat intake is undesirable in these cases, and that the glucose-tolerance curves are abnormal in pronounced essential hypertony.[2] We have succeeded in producing high blood-pressure in rabbits by feeding them on high calcium.[3]

The only possible conclusion from all these facts is that in hypertony there should be an all-round balanced diet of a low-calorie value. Clinical observation confirms that this is the proper dietetic régime. The fluid intake should not be restricted but should be copious.[4]

We are running in Liverpool an institute (established before the war) for the periodical examination of the normal; and the tendency has been, during the late years of the war and the post-war period, for the arterial pressure to become lower. The explanation is, I feel sure, the all-round decreased consumption of protein food. The low-protein intake of this period is very likely a factor, too, in the rise in the incidence of tuberculosis. We found that adolescents in particular require a very large amount of protein. This is the reason why I advocated some years ago the increase of the protein ration to people under 35 years of age at the cost of their elders. It may quite possibly be in the public interest that present supplies of meat should be distributed only among young people, and that the elderly should depend for protein intake on fish, eggs, &c.

RHEUMATIC FEVER AND MILK

SIR,—In your issue of March 11, Dr. Buchan suggested that boiling milk would render milk-borne streptococci non-antigenic.

While this may be true of some antigens, it is perhaps worth noting that for the past two years we have been preparing streptococci for animal inoculation by Thulin's method. In this method the organisms are heated for one hour to a temperature of approximately 120°C in an autoclave, and the resulting suspensions are fully antigenic when inoculated into rabbits.

R. M. CALMAN.

VITAMIN B_{12} AND PERNICIOUS ANÆMIA

SIR,—Dr. Hartley, in his letter of March 25, states that vitamin B_{12} alone has failed to produce remissions in *many* patients suffering from pernicious anæmia.

These results are of great interest as they are contrary to most of the findings so far published on the effectiveness of vitamin B_{12} or vitamin-B_{12} preparations in this condition. They are also at variance with my own experience. In 19 successive patients suffering from pernicious anæmia, vitamin-B_{12} preparations have produced remissions comparable with those seen in similar patients treated with the best liver extracts. Such experience is obviously limited, and it would be of great value to myself, and I am sure to other workers in this field, if he could give further details of the therapeutic failures to which he refers.

It is, of course, too early to be certain that vitamin B_{12} alone will be as effective as potent liver extracts for the maintenance therapy of patients with pernicious anæmia, and I would agree with him that, until more information is available, categorical statements on this subject are to be avoided. My experience to date has been that B_{12} is as satisfactory as parenteral liver extracts.

London, W.12.
D. L. MOLLIN.

AGAROL

SIR,—I should like to explode one or two myths in Mr. Warburton's letter of March 25.

The first point made by him seems to me so inaccurate that one is at a loss to see the reason for his making such a statement. Compare the price paid to the pharmacist for 'Agarol' and for emuls. paraff. liq. c. phenolphthal. (current price-list and Drug Tariff):

	Agarol 14 oz.		*Emuls. paraff. liq. c. phenolphthal.*
	Retail pack	*Dispensing pack*	
Net cost	4s. 6d.	4s. 6d.	1s. 11d.
33% increase as per Drug Tariff	1s. 6d.	1s. 6d.	8d.
Purchase-tax	1s. 6d.	Nil	Nil
	7s. 6d.	6s. 0d.	2s. 7d.

If the individual pharmacist can afford to buy six large bottles of agarol at once *for dispensing only*, he may buy it free of purchase-tax. The majority of pharmacists cannot afford to, and therefore pay tax and claim it back. But even without tax, agarol is nearly 2½ times the price of the official emulsion. The fact that prescriptions having a cost (including purchase-tax) less than 5s. are priced by average does not reduce the cost of agarol in any way If it so happens that the pharmacist is paid less for agarol than it costs him to buy (and this can only happen where prescriptions for agarol are few in number), it is a tribute to his public spirit that he continues to dispense rather than an argument in favour of prescriptions for agarol.

The *N.F.* formula is different; it contains more liqu
paraffin and less water than agarol.

Agarol may well be milled to a smaller particle-
but it is open to question whether this improv

diagnosis of "debility" or "neurasthenia" would cover hypertensive failures, thyrotoxicosis, or myxœdema.

The equipment of the surgery consisted of a kidney-dish, an ear syringe, a few test-tubes, a spirit-lamp, a metal spatula, a few needles, and a pair of scissors. There was no examination couch.

Nearby were two large well-equipped general hospitals, and several special hospitals and clinics. In a few clinics cases could be treated within a reasonable time—e.g., skins, ears, eyes, and chest surgery. The laboratory service worked well, and the bacteriological laboratory very well. But the medical clinics—particularly those for cardiac, gastric, and neurological cases—and several surgical clinics—notably the orthopædic department—had a waiting-list of two or three months. Even then the diagnostic procedures arranged in these outpatient departments often lasted for months because of the waiting-lists of other departments, especially the radiological. Very occasionally an urgent case would be taken out of turn. A possible short cut was to call in a consultant for a domiciliary visit, when earlier arrangements for special investigations were usually made. Many saw the consultant as private patients, and as a result there were consultants who were doing very well.

To arrange for a hospital admission I often had to spend 1–1½ hours on the telephone, and it was usually hopeless to attempt to get a tuberculous patient admitted—even if he was living in a community where he was almost bound to infect others. That nothing could be done about a medical and social emergency of this kind deserving the highest priority is a very grave reflection on our tuberculosis service. It was not much easier to find a bed for old folk, and in their homes they got little help in the way of fuel, blankets, or nourishment.

My own suggestions for dealing with the problems of such an area include the following:

Birth-control clinics should be set up, and to overcome shyness, a woman doctor from the clinic should *visit* the houses.

An investigation officer, with high personal—not academic—qualifications, should be responsible for instructing and helping women who are finding themselves unequal to the struggle of bringing up a family.

A welfare officer should be appointed who in an emergency would be able to help with money and stores, such as blankets, bedpans, sheets, and other utensils, at her own or the doctor's discretion without applying to higher authorities. She should also teach families the need for hygiene and cleanliness.

Together these three officers would give substantial help to the general practitioner.

The worst bottleneck in the work of the practitioner is the lack of X-ray facilities.

For a population of 200,000, for example, there should be an X-ray plant for taking films of their bones, teeth, and other minor conditions. These machines are not very expensive, and they would relieve the overburdened hospital X-ray department. Attached to this unit, and sharing dark-room facilities, there should also be a mobile electrocardiographic unit to help in detecting early cases of coronary thrombosis and in differential diagnosis. These units, and possibly a small physiotherapy department, could be housed in a prefabricated building.

With these aids the practitioner would be able to confirm his diagnosis, and to carry out with confidence a greater range of treatments. Hospital beds and outpatient clinics would be relieved and would be able to give more time to the more refined techniques. The current practice of referring a patient to an orthopædic surgeon for a film of a bone, or to a neurologist (with a three months' waiting-list) for a film of the skull, is absurd. The same applies to the diagnosis of heart and other diseases.

Competition for longer lists not only leads to neglect and omissions but also prevents the doctor from keeping up to date with medicine. The answer is, of course, to limit the numbers and increase the capitation fee. But, as Dr. Collings says, it is not enough to allow more practitioners to settle in the badly served industrial areas: these must be made professionally attractive. Also the doctor must be given a house on favourable terms, and a loan to cover his own and his family's living expenses for at least 6–9 months. The usual £300 will not even buy a secondhand car, and priority for new cars exists only in theory.

I heartily agree with Dr. Collings that assistants and trainee assistants should not work in practices of the kind I have described. Indeed nobody should. But more assistants should be allocated to good practitioners. There are still many practices which are admirably conducted, even, as Dr. Collings points out, providing their own laboratory facilities. But what emerges from his report is that the conscientious worker carries a greater load, a greater physical and mental strain, and far greater expenses, and finds in the end a smaller reward for himself. The well-trained and conscientious partner or assistant in the kind of practice described in the Collings report, and in this letter, is bound to lose either his job or his standard.

EX-ASSISTANT.

SIR,—Isn't it high time that a "Responsible Observer" was commissioned by the medical profession of this country to write a thirty-page report on the shortcomings of the medical men, and systems, of the United States of America? I think it should be rather good for our morale.

Leicester. J. K. M. DEAS.

Obituary

ARTHUR WILLIAM GARRARD BAGSHAWE

KT., C.M.G., B.A., M.B. CAMB.

Sir Arthur Bagshawe, who died in Cardiff on March 24 at the age of 78, was well known as an authority on tropical diseases. His name will always be associated with the Bureau of Hygiene and Tropical Diseases where he spent over 26 years of his working life, and it was under his wise guidance that the bureau grew from small beginnings to the established position it now enjoys.

[illegible]

Bagshawe was the second son of the Rev. Alfred Drake Bagshawe, rector of Wormhill, near Buxton. As a boy at Marlborough College he showed a strong bent towards natural history, and when at Caius College, Cambridge, he took a first class in part I of the natural sciences tripos. After he qualified from St. George's Hospital in 1895 there was some talk of his joining his uncle Frederic Bagshawe in a large practice at St. Leonard's-on-Sea, but the Colonial Medical Service attracted him as a career and in 1900 he became a medical officer of the Uganda Protectorate.

During his first years in Uganda he served on the Lango Expedition (1901), and with the Anglo-German Boundary Commission (1902–04). He was thus able to put to good use his interest in natural history, particularly in the local flora, and during his tours of duty made extensive collections of specimens of rare plants, which he gave to the British Museum (Natural History) in London. In 1906–07 he was employed on a special sleeping-sickness investigation in Uganda, and he was the first to discover the pupæ of *Glossina palpalis* in their natural breeding-grounds.

And what is the remedy for all this? Harangues and homilies are of no avail where great material advantages are to be gained in a country where the value of the pound gets less and less. Practice as it is today is as inevitable as the fact that night follows day and has been so since the panel system was instituted. The only check people understand is a financial one, and as time goes on and the country sinks lower and lower under the burdens imposed upon it by Socialism, some kind of means test will probably be found, and practice will again gravitate more towards private practice. Then, for the very simple and very obvious reason that doctors will have more time to practise it, general practice will rise to that state of excellence which Dr. Collings no doubt has in mind.

In the meantime, things being as they are and ourselves, willy-nilly, in the throes of trying to make a vast experiment work, we can only pray to be delivered from the unfair and superficial judgment of Dr. Collings, and sincerely, if perhaps somewhat rudely, echo the words once thrown by a critic at Keats, "Back to your gallipots, John."

Brighton. G. L. DAVIES.

SIR,—*Taking the tools away!*—After qualifying I took my fellowship and did seven years' hospital jobs before going into general practice. In 1938 I bought a mobile X-ray unit, which was useful to me, being 9 miles from the local infirmary. When the National Health Service came I offered my plant for use in my practice as part of the service: it was refused. The Special Areas Committee offered to buy it and I sold it to them. When an official from the Ministry of Works came to dismantle the plant, I asked him where it was going, and he told me it was being installed in the local mental hospital, where it now is. Meanwhile, there is a waiting-list of some weeks for "cold" X rays at the local infirmary."

RURAL PRACTITIONER.

SIR,—Dr. Collings's somewhat verbose report draws attention to some of the ills which beset general practice, and a good deal of it would have been equally true fifty years ago.

One of the things which tends to make general practice soul-destroying is the fact that "the customer is always right." Having to appear to be kindly and tolerant with that minority of patients which we all have, who come fussing to the surgery every time the proverbial finger aches, is responsible for the inordinately high death-rate among doctors from cardiovascular disorders. But we do not have the courage to take action. If one were to storm into the waiting-room at every surgery for only one week, and tell every patient to go to the devil, the work for a long time would be reduced by 50%, and it is doubtful if the financial loss would amount to 5%. The reason for this is that the same depressing faces can be seen week after week, with their owners sitting on their hyperkeratinised bottoms wearing holes in the seats of their pants.

I was in the Army during the war, and when I came back, my first surgery seemed to comprise the very same people as I had seen at the last one 3½ years previously. The prospect was so nauseating that I sold out at once and came to a new district.

Another aspect of this same snag is that quite a hopeless doctor with a kindly manner, who can sleep with his eyes open and fixed on the patient, and who talks as though he were pouring a mixture of honey, soft-soap, and goose-oil over the patient, will always have a big and financially successful practice. His neighbour, given "specialist ability" in every branch of medicine, will be the loser if he is forthright and abrupt in manner.

Dr. Collings is right when he draws attention to the failure of so many doctors to examine patients. This failure is not something which results from prolonged disillusionment in general practice, for it is very obvious in young doctors employed as assistants. It results from a slipshod mentality and a lack of conscience, and this type of person is not fitted for the responsibility of general practice. Ideally he should be relegated to posts where his work is permanently supervised.

On superficial examination, group practice would appear to be the answer to the specific points I have mentioned, because it would eliminate competition for patients, and the work of the doctors would be maintained at a higher level by purely professional competition with one another within the group. But we are "independents," and I can think of very few doctors with whom I could work in harmony for more than a few months.

Kidsgrove, Staffordshire. D. G. FRENCH.

SIR,—You are to be congratulated on publishing the report by Dr. Collings. One can only hope that his observations will be impressed on those who have the power to alter such bad conditions as he describes. In my opinion nothing in medical life requires higher priority.

Recently I spent some months as an assistant in a practice in a working-class district with many flourishing industries. In this district for many years there has been no unemployment, and the demand for female workers especially is still great. Housing conditions are extremely bad. Among the poorer families there are many with 4, 5, or more children, and usually the mother is expecting another baby. It is not surprising, therefore, that a large proportion of the patients are small children, inadequately looked after. Hygiene is poor. Half grown-up children sleep in the same room as their parents; only too often they witness unfortunate family scenes. During the day they spend their time in the street because there is so little space in the house.

My experience of this industrial practice supports the strictures made by Dr. Collings. During the crowded surgery hours patients were not examined—many had not been examined for years past—unless they complained of something above the neck or on the arms. Occasionally a small bare area over the top of the sternum in women, and a still smaller area around the centre of the sternum in men, was bared to the stethoscope. But at most the patient undid one button of his shirt and vest, without removing his overcoat. For severe headache over a long period tab. codeini co. was prescribed: the underlying cause was hardly looked for. Little attempt was made to investigate the many causes of cough; but more linctus flows through general practice than water through the Thames!

The local chemist used to hand out a couple of gallons of the four main linctuses per week; 1 in every 8 prescriptions called for 4 oz. of a linctus. Many patients came week after week for their bottle, which they seemed to take as a sort of extra nourishment. Heart-failure, tuberculosis, neoplasms, bronchiectasis, and silicosis were generally far advanced before they were recognised as the cause of a cough.

Often a mother would come to the surgery to ask for a bottle of medicine for her child with diarrhœa. Some magnesia or kaolin was prescribed; and when she called the doctor a day or two later the actual diagnosis would turn out to be pneumonia. Many patients sent their relatives or friends for weeks and months on end for certificates and prescriptions.

Visits had to be made at high speed and there was little time to investigate complicated cases. There was no time to bother with bedsores and similar ailments. Waterlogged patients who could have been relieved by a few injections of mercurials were left waterlogged and seen again on routine visits at monthly intervals. A

Notes and News

ART FOR MEDICINE'S SAKE

MEDICAL artists (not to be confused with members of the Medical Art Society) held a first exhibition of their work at the Royal Society of Medicine between March 28 and April 1—a skilful but macabre entertainment. These drawings of lesions, dissections, dead organs, and dying patients are so vivid and faithful that they disquiet even the seasoned onlooker: they are certainly more disturbing than a greyish specimen in a pot. The level of care and accuracy was very high, and it would not be easy to distinguish particular contributors, even if the absence of a catalogue had not added to the difficulty. Several good and ingenious diagrams were shown, and some first-class wax models of skin lesions had a conspicuous place. Some description of the way in which these were made would have been welcome.

The hon. secretary of the Medical Artists Association of Great Britain, which arranged the exhibition, is Mrs. Blackburn, 19, York Avenue, East Sheen, London, S.W.14.

BLOOD-LETTING FILMED

THE instruments used by the profession to let blood have a historical if slightly gruesome interest. Various tools of the kind, including a lancet, are shown as an introduction to a short film, sponsored by Bayer Products Ltd., on *The Taking of Blood*. The rest deals in detail with the technique of blood withdrawal by means of a syringe, and also by means of the Bayer 'Venule'—a neat little device, especially convenient for those who have to send specimens by post. It consists of a sterile needle, covered by a glass cap, sealed into a glass tube passing through the rubber cap of an evacuated test-tube. The glass cap is filed off, the needle inserted into the vein, and the tube tilted at an angle to it; this manœuvre releases a simple valve and allows the blood to be sucked into the tube. As soon as enough has been withdrawn the valve is allowed to close again, the needle is removed from the vein and the needle holder is filed off. The tube can then be placed in the box supplied and posted off. The action of the valve is nicely illustrated by animated diagrams.

The film has been made for Bayer by the Kinocrat Film Unit, and is intended for showing to doctors, medical students, nurses, and others interested.

GENITAL MYIASIS

THE flesh-fly (*Cochliomyia hominivorax*), which ranges widely in America, lays its eggs in living flesh, usually the mouth, the nose, or an open sore, especially one with an offensive discharge. In 1926 Greenway and Marciano[1] described myiasis of the vulva caused by *C. macellaria*, but these two flies were at that time confused, and *C. hominivorax* must have been responsible, because *C. macellaria* lays its eggs only in carrion. Since then many cases of myiasis of the female genitalia have been reported from South America. Of these, the 12 Argentine cases are summarised by Niño,[2] who adds to them yet another case of vulval infestation. The labium majus was the infested site in 6 of the 13 cases, the clitoris in 3, the labium minus in 2, the urethral meatus in 1, and the uterus in 1. In 6 of the cases the predisposing factor was supposed to be either a menstrual or a pathological discharge; in 2 it was a skin disease; in 4 none was found.

University of Sheffield

On March 25 the following degrees were conferred:

M.D.—H. J. Whiteley.

M.B., Ch.B.—J. D. S. Hammond (with first-class honours); E. A. Badoe, Stella M. Benson-Cooke, E. R. Bowler, Lorna Chippindale, Sheila R. S. Cooper, C. K. Crawford, George Dalton, Margaret R. Davies-Jones, Dora C. Dean, M. W. L. Dibb, J. A. Greenwood, Basil Hirst, P. A. Isherwood, Katherine B. Laird, A. J. Moore, Moreen C. O'Brien, S. S. Scott, Yves J. F. Sojka, C. R. Thickett, W. D. Turner, Audrey J. Warren.

University of Manchester

The following appointments have been made: Dr. G. T. Ashley and Dr. Roger Warwick, lecturers in anatomy; Dr. M. D. Milne, lecturer in medicine; Dr. L. A. Liversedge, [illegible] in medical neurology; Dr. J. L. S. Smith, assistant [illegible]hthalmic pathology; Dr. Eleanor Schill, medical [illegible]men students in the department of education.

Royal College of Surgeons

At the annual dinner of the Faculty of Anæsthetists, held at the college on March 29, Mr. A. D. Marston, the dean, spoke with pleasure of the increasing coöperation between the Royal Colleges and the British Postgraduate Medical Federation. Casting his mind back to 1800, when the college received its first Royal charter as an independent body, he observed that then nothing could have seemed more improbable than that one day it would have a faculty of anæsthetists. Sir Cecil Wakeley, replying on behalf of The College, referred to the important work done by Lord Moran not only for his own college but for medicine during the years he had presided over the Royal College of Physicians. He went on to say that in anæsthesia great advances had been made in the past decade; and he insisted that progress in surgery went hand in hand with progress in anæsthesia. The surgeon looked to the anæsthetist for help both before and after operation; only thus could mortality and complications be reduced. The faculty had done great work in the two years since it was founded. Sir Harry Platt, who proposed The Faculty, recalled the early work of Simpson in Edinburgh, and of Morton, the Boston dentist, and pictured anæsthesia being born by obstetrics out of dentistry. Referring to the Collings report, he said that this had come as a great shock; the widening gulf between general practitioners and specialists must be closed, and he suggested that practitioners might work beside specialists. In reply Dr. Bernard Johnson, the vice-dean, observed that anæsthetists were now the strongest link between pure medicine and pure surgery. Prof. Lillian Penson and Sir John Charles replied for The Guests to a toast proposed by Dr. John Gillies.

Royal College of Obstetricians and Gynæcologists

A postgraduate course of lectures for those studying the special practice of obstetrics and gynæcology will be given at the college, 58, Queen Anne Street, London, W.1, on April 14 and 15, and on April 28 and 29. Further particulars may be had from the secretary of the college.

Faculty of Homœopathy

A meeting of the faculty will be held at the Royal London Homœopathic Hospital, Great Ormond Street, London, W.C.1, on Thursday, April 13, at 5 P.M., when Dr. Duncan Russell will speak on Calcium Compounds.

British Orthopædic Association

The spring meeting of the association will take place in Cardiff on April 21 and 22, under the presidency of Mr. S. L. Higgs.

Territorial Army Medical Officers' Association

A meeting of this association will be held at 2.30 P.M. on May 20, at the Royal Army Medical College, Millbank, London, S.W.1. Invitations to attend have been sent on behalf of the committee to D.Ds.M.S., A.A. Command, A.Ds.M.S., officers in charge of units, and honorary colonels.

Institute of Child Health

This institute's report for 1949 records the retiral from the position of dean of Dr. W. G. Wyllie, who has been succeeded by Dr. G. H. Newns. The new academic board has set up a subcommittee to consider how the teaching arrangements can be improved; and it is proposed to try offering some of the postgraduate students "clinical clerkships" in the wards for part of each term.

Heberden Society

This society met on March 10 at the Royal Infirmary, Manchester, at the Rheumatism Research Centre, with Dr. J. H. Kellgren as the host, and Dr. W. S. C. Copeman, the president, in the chair. Dr. Oscar Janus read a paper on the Assay of Rapidly Acting Remedies in Rheumatoid Arthritis, discussing methods by which it might be possible to recognise the potency of, for example, A.C.T.H., even when given in doses so small that no obvious clinical effect is apparent. Dr. Kellgren showed a film illustrating the effects of A.C.T.H. in a case of rheumatoid arthritis. Among other communications was one from Dr. J. S. Lawrence on Preliminary Findings of the Walkden Survey, which is being carried out in association with the department. On the following day visits were paid to the Walkden Miners' Clinic and the Devonshire Royal Hospital, Buxton.

In 1907–08 an International Conference on Sleeping Sickness met in London to discuss the possibility of establishing a central international bureau "to extract and circulate all new literature on sleeping-sickness" to research-workers and field investigators. This international bureau failed to materialise, but the Secretary of State for the Colonies decided to set up a British bureau, of which Bagshawe became the first director in 1908. He began work in a single room put at his disposal by the Royal Society in Burlington House. The total funds provided for running the bureau were £1000 a year, out of which fell to be paid Bagshawe's salary and that of any clerical assistant he might need, as well as the printing bills for the monthly *Sleeping Sickness Bulletins*, and all other running expenses. So near the bone was this allocation that when the question arose of buying a carpet for the one room used by the bureau it was decided to ask the Royal Society to pay for it, on the understanding that the carpet would become the society's property if the bureau were to leave. The need of employing translators for foreign papers, and thus incurring further expense, was ruled out by Bagshawe offering to spend "three weeks' vacation in Germany in order to increase his familiarity with the German language."

During his first four years as director of the Sleeping Sickness Bureau, Bagshawe produced four valuable volumes containing articles treating special aspects of trypanosomiasis in some detail, and abstracts of the current literature, as well as an exhaustive bibliography and maps showing the known distribution of sleeping-sickness and of tsetse flies in Africa. He wrote the whole of the articles and the abstracts in the *Sleeping Sickness Bulletins* himself, and the care he gave to their preparation set up new standards in medical abstracting.

In 1912 the scope of the bureau was enlarged to cover all tropical diseases. Later there was a further extension on the hygiene side, which Bagshawe, whose interests in hygiene had led him to work for the D.P.H. in 1908, welcomed. He continued as editor of both the *Tropical Diseases Bulletin* and the *Bulletin of Hygiene* until his retirement in 1935.

He was an original fellow of the Royal Society of Tropical Medicine and Hygiene, and he held office as honorary secretary (1917–21), treasurer (1925–35), and president (1935–37). He was for a time a member of an expert committee of the Health Committee of the League of Nations dealing with tuberculosis and sleeping-sickness in Equatorial Africa. He was appointed C.M.G. in 1915, and he was awarded the Mary Kingsley medal of the Liverpool School of Tropical Medicine in 1920. In 1933 he received a knighthood.

He married in 1910 Alice Mary Thornber, who died in 1944, and they had two sons. His elder son, who served with a Guards battalion during the war, had lately taken up dairy-farming in South Wales, where Sir Arthur had joined him about a year ago. R. L. S.

LIONEL ALFRED DINGLEY

M.D. LOND., F.R.C.S.

Mr. Dingley, who died on March 16 at the age of 61, was senior surgeon to the West Bromwich and District Hospital and visiting surgeon to the Hallam Hospital. Son of E. A. Dingley, M.D., J.P., he was born at Wednesbury and went from Epworth College, Rhyl, to University College, London. At University College Hospital he won the Fellowes gold medal and the prize for clinical surgery, and in 1912 and 1913 was house-physician to Risien Russell and house-surgeon to Rickman Godlee. He served as a Territorial in the R.A.M.C. from 1914 to 1918, reaching the rank of major and receiving the Belgian croix-de-guerre. He took his F.R.C.S. in 1920 and settled in general practice. His work thereafter is described in the following tribute from L. G. P.

"Although Lionel Dingley could have pursued a surgical career, he deliberately chose the life of a family doctor and joined his father in a busy general practice in Wednesbury. An element of filial devotion may have entered into his decision, because he always aspired to reach and, in fact, did reach the high standard of medical practice and conduct set by his father. The chief reason for his choice was, however, that he believed he could give more service to the community in general, than in consulting, practice and his whole life was a striking demonstration of the fact that 'it is more blessed to give than to receive.' He was an ideal family doctor and was beloved by his patients, to whom his great ability was freely given and he became their confidant and adviser. Throughout his life he never lost his boyish enthusiasm and sense of humour and his bright smile brought cheer and comfort into many a sickroom; particularly when the occupant suffered from a hopeless condition.

"After some years in general practice, he was appointed surgeon to the West Bromwich and District General Hospital and then was able to make full use of his surgical training and ability. The combined duties of a general practitioner and a surgeon to a general hospital entailed extremely hard work, but he revelled in it and it would be difficult to have found a better example of the general-practitioner surgeon. The present high standing of the hospital is largely, if not entirely, due to his drive, ability, and vision. Under his direction it was enlarged and partly rebuilt, the staff increased and strengthened, and its work greatly expanded; indeed, the present hospital can rightly be regarded as a memorial to him.

"To his great delight, he was chosen by the Minister of Health to be one of the original members of the Birmingham Regional Hospital Board, and looked forward to devoting a considerable part of the time of his retirement to the work of the board. I first heard of his illness at a meeting of the board at which he arrived late. He sat next to me and, greeting me with his usual smile, said 'I am sorry I am late, but I have just been sigmoidoscoped and have a carcinoma of the rectum.' Afterwards he said 'This could not have come at a better time. I have my wife settled in our cottage and the children have decided on their future.' This conversation was absolutely typical of his whole attitude towards a distressing and fatal illness and the basis of this attitude was a radiant Christian faith. One of the reasons which determined his choice of the delightful house in the beautiful countryside which was his home for such a short time was the fact that he could spend many of his Sundays preaching in small Methodist country chapels. It is sad to think that he had so few opportunities of realising this ambition.

"He had an extremely happy family life, both before and after marriage. He married rather later in life than is usual, but he leaves a son who is now studying medicine and a daughter who is about to take up a nursing career."

Appointments

Curr, J. F., M.D. Edin., F.R.C.S.E.: civilian specialist in surgery for the Army.

Hatherley, L. I., M.R.C.S.: civilian specialist in surgery for the Army.

Keenan, Donal, M.B.: temp. junior house-physician, Castlerea Sanatorium, Roscommon, Eire.

McGorry, H. D., B.A., M.D. Dubl., D.P.H.: asst. M.O., Castlerea Sanatorium, Roscommon, Eire.

Peach, A. N. H., M.B. Brist., F.R.C.S.: civilian specialist in surgery for the Army.

Pierce, J. W., M.D. Lond., M.R.C.P., D.M.R.D.: radiologist (cons.), X-ray diagnostic department, St. Thomas's Hospital, London.

Appointed Factory Doctors:

Candler, T. O., M.B. Camb., F.R.C.S.: Wells district, Somerset.

Circuit, Kathleen, B.A. Lond., M.R.C.S.: Framlingham district, Suffolk.

Lilly, R. G., M.B. Durh.: Long Buckby district, Warwickshire.

Robb, D. F., M.R.C.S.: Perranporth district, Cornwall.

Robinson, R. A., M.B.: Castleton district, Yorks.

Williams, P. E., B.SC. Wales, M.R.C.S.: Clynderwen district, Pembroke.

Colonial Service:

Afori-Atta, S. B. G., M.B.: lady M.O., Gold Coast.

Bell, Fairfax, M.A., B.M. Oxfd, D.T.M. & H.: M.O., Kenya.

Chhung Hin, A. K. N., M.B., D.T.M. & H.: senior pathologist, Mauritius.

Davies, C. W., M.R.C.S., D.P.H.: senior M.O., Tanganyika.

Dodds, G. E., B.A., M.B. Dubl., D.O.M.S.: senior specialist, Nigeria.

Fung-Kee-Fung, C. O., M.B. Lond., F.R.C.S., D.OBST.: surgeon specialist, British Guiana.

Gilles, E. C., L.R.C.P.E.: regional deputy director of medical services, Nigeria.

Keating, S. R., M.B. N.U.I.: M.O. orthopædic, Kenya.

Kerr, W. G., M.B. Edin., F.R.C.S.E.: surgical specialist, Tanganyika.

Montgomery, T. H. L., M.B. Belf., D.P.H., D.T.M. [illegible] director of medical services, Nigeria.

Rendle-Short, Coralie, M.B., CH.M. Brist., M.R.C.[illegible] logical and obstetrical specialist, Hong Kong.

Tassis, J. A., M.D. Vienna: M.O., Federation of [illegible]

Trim, E. A., M.D. Camb., D.T.M. & H.: deput[illegible] services, Kenya.

PREGNANCY AND PULMONARY TUBERCULOSIS *

H. MIDGLEY TURNER

M.D. Manc., M.R.C.P., D.P.H.

CONSULTANT CHEST PHYSICIAN, SHEFFIELD REGIONAL HOSPITAL BOARD; LECTURER IN TUBERCULOSIS IN THE UNIVERSITY OF SHEFFIELD

BEFORE 1930 the view most generally held was that pregnancy in a tuberculous woman was a disaster. This view was neatly expressed by Young (1926): "For the virgin no marriage, for the married no pregnancy, for the pregnant no confinement, for the mother no suckling." But opinion has changed. It is not now believed that tuberculosis need be a bar to marriage, or that pregnancy should not be allowed or even encouraged in a quiescent case of tuberculosis; and lactation is only contra-indicated where there is a danger of infecting the baby.

This remarkable change in medical opinion has taken place gradually. One of the good papers which challenged the old view was that of Hill (1928), who made a statistical study of pregnancies in 349 women where the pregnancy occurred either during or immediately before active tuberculosis. From this study he concluded that pregnancy had no appreciable effect on the progress of the tuberculosis disease.

Cohen (1943), reporting on the effect of pregnancy and parturition in 100 cases of pulmonary tuberculosis, of which 25 had active disease, states that active tuberculosis is seldom accelerated by pregnancy and labour, and that abortion is not to be advised simply because the woman is known to have had tuberculosis.

My own special interest in this subject goes back to twenty-one years ago. I was then called in consultation on a young married woman who at the third month of pregnancy developed an acute tuberculous lesion in one lung and was having hæmoptysis. I advised immediate abortion, to be followed by admission to a sanatorium, and possibly collapse therapy later. For various reasons her doctor could not terminate the pregnancy until it was about four and a half months advanced. The abortion was then induced, and the patient died from shock and postoperative hæmorrhage.

I report here the results of my observations since then, based on 718 pregnancies in 534 different tuberculous women, of whom 163 are known to have died of pulmonary tuberculosis. Many of the others have been followed for periods up to ten years after pregnancy. Details of the series of pregnancies are given in table I. Each pregnancy is treated as a separate episode, and survival percentages are worked out for yearly intervals after the episode.

CLASSIFICATION

Pregnancies have been grouped into four categories:

(1) Pregnancy in a woman known to have active tuberculosis at the time of conception.

(2) Pregnancy in a woman known to have quiescent tuberculosis at the time of conception.

(3) Tuberculosis first diagnosed during pregnancy.

(4) Tuberculosis first diagnosed within a year of the termination of a pregnancy.

In groups 1 and 2 survival is dated from the start of pregnancy. In groups 3 and 4 survival is dated from the diagnosis of tuberculosis.

TABLE I—DETAILS OF PREGNANCIES ASSOCIATED WITH PULMONARY TUBERCULOSIS

—	Pregnancy in active tuberculosis	Pregnancy in quiescent tuberculosis	Tuberculosis diagnosed in pregnancy	Tuberculosis diagnosed within a year after pregnancy	Total
Pregnancies	240	220	78	180	718
Live births *	196	204	70	171	641
Stillbirths	5	3	—	2	10
Induced abortions ..	20	0	5	0	25
Spontaneous abortions ..	18	13	3	10	44
[illegible] ..	2	..	1	..	3
[illegible] section †	11	4	..	..	15
Neonatal deaths	7	9	3	8	27
Deaths under 3 Years:					
Tuberculosis	9	2	0	21	32
Bronchopneumonia ..	4	..	1	1	6
Infective enteritis ..	3	1	2	1	7
Laryngitis	1	..	..	..	1
Diphtheria	..	1	..	..	1
Measles	..	1	..	..	1
Bronchitis	1	..	..	..	1
Hydrocephalus ..	1	..	..	..	1
Prematurity ..	1	..	..	..	1
Poliomyelitis ..	..	..	..	1	1
Cause unknown ..	3	..	..	..	3
Total deaths under 3 years	30	14	6	32	82

* 5 twins. † Includes 1 stillbirth.

ONSET OF LABOUR

In groups 1–3 labour tended to begin early, but this tendency was not very obvious. Of 264 pregnancies proceeding to term with active tuberculosis, in 43 (17%) labour began in the 38th week or earlier, whereas in 31 (12%) it began in the 41st week or later. The corresponding figures for 203 pregnancies in quiescent tuberculosis were 31 (15%) in the 38th week or earlier and 22 (11%) in the 41st week or later. The chances of spontaneous abortion or stillbirth seem to be rather greater where the tuberculosis is active than where it is quiescent.

TABLE II—SURVIVAL AFTER PREGNANCY

—		Years after pregnancy									
		1	2	3	4	5	6	7	8	9	10
Pregnancy in active tuberculosis	Pregnancies Living ..	240 229 *(95%)*	228 204 *(89%)*	218 173 *(79%)*	194 142 *(73%)*	177 113 *(64%)*	146 96 *(66%)*	127 78 *(61%)*	117 70 *(60%)*	115 67 *(58%)*	114 63 *(55%)*
Pregnancy in quiescent tuberculosis	Pregnancies Living ..	220 219 *(99%)*	188 186 *(99%)*	164 161 *(98%)*	138 134 *(97%)*	111 105 *(95%)*	91 85 *(93%)*	70 64 *(91%)*	59 53 *(90%)*	53 47 *(89%)*	51 44 *(86%)*
Tuberculosis diagnosed during pregnancy	Pregnancies Living ..	78 69 *(88%)*	73 62 *(85%)*	63 50 *(79%)*	51 37 *(73%)*	46 31 *(67%)*	40 23 *(58%)*	34 18 *(53%)*	27 14 *(52%)*	27 14 *(52%)*	27 14 *(52%)*
Tuberculosis within a year after pregnancy	Pregnancies Living ..	180 160 *(89%)*	160 116 *(73%)*	130 83 *(64%)*	117 67 *(57%)*	100 52 *(52%)*	94 47 *(50%)*	83 40 *(48%)*	75 35 *(47%)*	72 32 *(44%)*	68 29 *(43%)*

---

* Presidential address to the Sheffield Regional Chest Society.

British Association of Physical Medicine

Mr. Bernard Baruch, of New York, has given the Association £1000, to be used as its president, Lord Horder, may suggest.

Naval Medical Compassionate Fund

A meeting of the subscribers of this fund will be held at 2.30 P.M. on April 21 at the Medical Department of the Navy, Queen Anne's Mansions, St. James's Park, London, S.W.1, to elect six directors of the fund.

International Conference on Speech Therapy

This conference will be held in Amsterdam from Aug. 21 to 26. The speakers will include Prof. T. Pomfret Kilner. The secretary of the conference is Dr. Hanny Veldkamp, 27 P.C. Hooftstraat, Amsterdam-Z, Holland.

Dental Treatment for School-children

The council of the British Dental Association has appealed to its members to organise their own priority service for school-children "until such time as the Ministries of Health and Education and the local authorities have risen to their responsibilities by providing a proper service for the children." Members are recommended to set aside not less than one half-day each week solely for the treatment of school-children who are unable to obtain dental treatment through the school dental service.

Photography and Cinematography by Invisible Radiation

A conference on this subject is to be held on Saturday, April 15, at 10 A.M. at the London University Institute of Education, Malet Street, W.C.1. Dr. E. Rowe, of the Royal Cancer Hospital, will discuss the Observation by Ultraviolet Micrography of fresh Unfixed Tissue and of the separated Tumour Agent from the Rous Fowl Sarcoma. Dr. R. Barer, of the University of Oxford, in his paper on Learning about the Invisible, will deal with both ultraviolet and infrared microphotography. Dr. Russell Reynolds will speak on X-ray Cinematography. Further information may be had from the secretary of the Scientific Film Association, 4, Great Russell Street, W.C.1.

Award to R.A.F. Officer

The George Medal has been awarded to Acting Squadron-Leader R. E. Woolley, M.R.C.S.

In a severe thunderstorm at Seletar, a R.A.F. maintenance base in the Far East, on the night of Nov. 20, a Sunderland flying-boat crashed in shallow water. Braving petrol fire risks, Squadron-Leader Woolley extricated two badly injured members of the crew who were trapped. The pilot could not be released, and, assisted by another officer, Woolley prepared to amputate his foot. In an inaccessible position, with a hand-lamp as the only illumination, he worked for twenty minutes while the pilot, who was under morphine, had his head supported clear of the water. A single spark from the surgeon's saw striking the wreckage might have started a petrol fire from which there could have been little hope of escape. The fumes were overpowering, but the operation was completed and the pilot sent to hospital. He died next morning.

Squadron-Leader Woolley qualified from St. Mary's Hospital in 1946.

Faculty of Ophthalmologists

At a meeting of the council on March 9 it was reported that letters of protest from the chairman of the British Orthoptic Society and the faculty had been sent to the Minister of Health strongly deprecating the recent decision to exclude orthoptists from consideration jointly with other medical auxiliaries. Consternation was expressed concerning the attempt to bracket orthoptists with opticians, because opticians are not medical auxiliaries and are not hospital-trained. Approval was expressed for the Contact Lens Society's recent resolution "that attention be drawn to the necessity for the elimination of unqualified practice in contact lens work and to request the various bodies giving evidence before the Interdepartmental Committee to point out this need." A suggestion that the faculty should issue a ruling about the method of prophylaxis against ophthalmia neonatorum was rejected, on the grounds that (*a*) opinions differed considerably on the subject, and (*b*) the council might thereby lay itself open to the charge of attempted regimentation.

The following have been elected to the council to fill vacancies: Dr. Dorothy R. Campbell, Mr. J. D. M. Cardell, Mr. R. Affleck Greeves, Mr. T. Keith Lyle, Mr. A. B. Nutt, and Dr. G. I. Scott.

Travelling Awards in Ophthalmology and Otology

The Medical Research Council invites applications for travelling awards in these specialties for 1950–51 to be provided from the Alexander Pigott Wernher Trust.

These awards are intended for medical graduates who have had some training in research work in ophthalmology or otology. In general, fellowships will be tenable for periods of up to a year for specific research, but grants may also be given for short-term visits abroad to study methods of investigation and treatment. Fellowships will as a rule provide for appropriate subsistence allowance and travelling expenses, whereas grants for short-term visits (up to three months) will ordinarily cover travelling expenses only.

Applications should be sent to the secretary of the council, 38, Old Queen Street, London, S.W.1, by June 1, 1950.

The staff of the Tavistock Clinic announce that there will be no course for general practitioners in the coming summer term. They hope to hold such a course again in the 1950–51 session.

Diary of the Week

APRIL 9 TO 15

Tuesday, 11th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. B. T. Parsons-Smith: Cardiac Failure. (First Lumleian lecture.)

Wednesday, 12th

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel: Postgraduate lecture-demonstration.

Thursday, 13th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. Parsons-Smith: Cardiac Failure. (Last Lumleian lecture.)

NORTH-EAST LONDON CLINICAL SOCIETY
8.15 P.M. (Prince of Wales's General Hospital, N.15.) Dr. L. E. Glynn: Nutrition and Liver Disease.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY, Stepney Green, E.1
3 P.M. Dr. G. I. M. Swyer: Obesity.

Friday, 14th

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS, 58, Queen Anne Street, W.1
NOON. Dr. Clifford Kennedy: Incoördinate Uterine Action.
3 P.M. Mr. C. W. A. Kimbell: Abdominal Hysterectomy.
5 P.M. Mr. G. F. Gibberd, Mr. A. C. Bell, Mr. J. Howkins, Dr. S. D. Loxton, Mr. Leslie Williams: Any Questions?

BIOCHEMICAL SOCIETY
3.15 P.M. (University College, Dublin.) Short papers.

Saturday, 15th

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS
9.45 A.M. Mr. H. Harvey Evers: Malignant Ovarian Tumours.
11.30 A.M. Prof. E. M. Robertson: Early Diagnosis of Cancer.

Births, Marriages, and Deaths

BIRTHS

AKEROYD.—On March 26, at Harpenden, the wife of Dr. Alan Akeroyd—twin daughters.

DOUGLASS.—On March 25, in London, the wife of Dr. D. J. Douglass—a son.

EVANS.—On March 25, in London, the wife of Dr. G. M. H. Evans—a daughter.

GLANCY.—On March 25, at Salford, the wife of Dr. C. J. Glancy—a son.

GOW.—On March 26, the wife of Dr. I. M. Gow—a daughter.

REYNOLDS.—On March 28, at Ugley, the wife of Dr. S. R. Reynolds—a daughter.

TITCOMBE.—On March 26, the wife of Dr. J. M. Titcombe—a son.

TODD.—On March 27, at Guildford, the wife of Dr. J. W. Todd—a son.

DEATHS

BAGSHAWE.—On March 24, in Cardiff, Arthur William Garrard Bagshawe, KT., C.M.G., B.A., M.B. Camb., D.P.H.

FELIX.—On March 22, in London, Theodore James Felix, M.R.C.S., aged 25.

LITTLEDALE.—On March 27, at Charing, Kent, Herbert Edward Littledale, B.A., M.D. Dubl., aged 77.

MARTIN.—On March 27, in Edinburgh, George Ewart Martin, M.A., M.B. Edin., F.R.C.S.E.

PIDCOCK.—On March 23, Bertram Henzell Pidcock, M.B. Lond., F.R.C.S.

WILLIAMS.—On March 25, at Aberystwyth, Moses Thomas Williams, M.B. Lond., F.R.C.S., aged 73.

PREGNANCY AND PULMONARY TUBERCULOSIS *

H. MIDGLEY TURNER
M.D. Manc., M.R.C.P., D.P.H.
CONSULTANT CHEST PHYSICIAN, SHEFFIELD REGIONAL HOSPITAL BOARD; LECTURER IN TUBERCULOSIS IN THE UNIVERSITY OF SHEFFIELD

BEFORE 1930 the view most generally held was that pregnancy in a tuberculous woman was a disaster. This view was neatly expressed by Young (1926): "For the virgin no marriage, for the married no pregnancy, for the pregnant no confinement, for the mother no suckling." But opinion has changed. It is not now believed that tuberculosis need be a bar to marriage, or that pregnancy should not be allowed or even encouraged in a quiescent case of tuberculosis; and lactation is only contra-indicated where there is a danger of infecting the baby.

This remarkable change in medical opinion has taken place gradually. One of the good papers which challenged the old view was that of Hill (1928), who made a statistical study of pregnancies in 349 women where the pregnancy occurred either during or immediately before active tuberculosis. From this study he concluded that pregnancy had no appreciable effect on the progress of the tuberculosis disease.

Cohen (1943), reporting on the effect of pregnancy and parturition in 100 cases of pulmonary tuberculosis, of which 25 had active disease, states that active tuberculosis is seldom accelerated by pregnancy and labour, and that abortion is not to be advised simply because the woman is known to have had tuberculosis.

My own special interest in this subject goes back to twenty-one years ago. I was then called in consultation on a young married woman who at the third month of pregnancy developed an acute tuberculous lesion in one lung and was having hæmoptysis. I advised immediate abortion, to be followed by admission to a sanatorium, and possibly collapse therapy later. For various reasons her doctor could not terminate the pregnancy until it was about four and a half months advanced. The abortion was then induced, and the patient died from shock and postoperative hæmorrhage.

I report here the results of my observations since then, based on 718 pregnancies in 534 different tuberculous women, of whom 163 are known to have died of pulmonary tuberculosis. Many of the others have been followed for periods up to ten years after pregnancy. Details of the series of pregnancies are given in table I. Each pregnancy is treated as a separate episode, and survival percentages are worked out for yearly intervals after the episode.

CLASSIFICATION

Pregnancies have been grouped into four categories:

(1) Pregnancy in a woman known to have active tuberculosis at the time of conception.

(2) Pregnancy in a woman known to have quiescent tuberculosis at the time of conception.

(3) Tuberculosis first diagnosed during pregnancy.

(4) Tuberculosis first diagnosed within a year of the termination of a pregnancy.

In groups 1 and 2 survival is dated from the start of pregnancy. In groups 3 and 4 survival is dated from the diagnosis of tuberculosis.

TABLE I—DETAILS OF PREGNANCIES ASSOCIATED WITH PULMONARY TUBERCULOSIS

—	Pregnancy in active tuberculosis	Pregnancy in quiescent tuberculosis	Tuberculosis diagnosed in pregnancy	Tuberculosis diagnosed within a year after pregnancy	Total
Pregnancies	240	220	78	180	718
Live births *	196	204	70	171	641
Stillbirths	5	3	—	2	10
Induced abortions	20	0	5	0	25

Prematurity	1	..	..	..	1
Poliomyelitis	..	..	..	1	1
Cause unknown	3	..	..	..	3
Total deaths under 3 years	30	14	6	32	82

* 5 twins. † Includes 1 stillbirth.

ONSET OF LABOUR

In groups 1–3 labour tended to begin early, but this tendency was not very obvious. Of 264 pregnancies proceeding to term with active tuberculosis, in 43 (17%) labour began in the 38th week or earlier, whereas in 31 (12%) it began in the 41st week or later. The corresponding figures for 203 pregnancies in quiescent tuberculosis were 31 (15%) in the 38th week or earlier and 22 (11%) in the 41st week or later. The chances of spontaneous abortion or stillbirth seem to be rather greater where the tuberculosis is active than where it is quiescent.

* Presidential address to the Sheffield Regional Chest Society.

embedding of the ovum and placental development. Browne et al. (1939) found low gonadotropin levels in early abortion, whereas Jeffcoate (1932) found that some cases of inevitable abortion were associated with an excess of œstrogen in the body-fluids. If these findings are correct, and spontaneous abortion in a substantial proportion of cases is associated with either a deficiency of gonadotropin or an excess of œstrogen, the favourable survival-rates in tuberculosis associated with spontaneous abortion can be explained by the hormonic theory outlined above, in that the very factor which is inimical to the pregnancy exerts a favourable influence on the tuberculosis.

It appears incontrovertible that the first four months of pregnancy and the weeks immediately succeeding parturition are the only periods in pregnancy during which any special risk regarding tuberculosis exists. The theory has been advanced that these potential dangers are due to the fact that excess of gonadotropin is an adverse factor and excess of œstrogen a favourable factor, the sudden withdrawal of which, in the presence of a high gonadotropin level, may exert an unfavourable influence, particularly during the period of debility in the puerperium. If this is accepted, it is difficult to justify the induction of abortion once the phase of gonadotropic domination has passed and the phase of œstrogen domination has begun. Perhaps the phase of œstrogenic domination is responsible for those cases in which pregnancy leads to improvement in the tuberculosis. In practice this means that little advantage is to be expected from terminating a pregnancy later than the 14th week. This has been my own view for many years, but mainly on the grounds that with each week after the first trimester the risks of abortion increase while the advantages do not seem to increase. Now there seems to be a more rational scientific reason for restricting induction of abortion to cases in which it is indicated in the first trimester. It also seems that, if pregnancy must be terminated, the earlier in the first trimester at which it can be terminated the greater is the probable advantage.

The modern practice of administering gonadotropic substances to counteract a tendency to early abortion is one which also requires very careful consideration if the patient shows evidence of past or present tuberculosis. On the other hand, the exhibition of œstrogenic substances, such as stilbœstrol immediately after parturition where suppression of lactation is desired, may be beneficial to the tuberculous woman by lessening the impact of the sudden fall in œstrogen level which normally takes place at this time. It is a common practice, and has for long been my own practice and the practice of my obstetrical colleagues, to suppress lactation in this way in active tuberculosis where suckling would be dangerous to the baby. It may well be that this action, which has in the past been dictated by the welfare of the baby, has also an advantage for the mother which more than counterbalances the loss of the tonic effects of lactation on involution of the uterus. Here is a point which merits investigation: would administration of œstrogen for a period after parturition in women with active tuberculosis assist in countering the special dangers of the puerperium?

CONCLUSION

Clinical observations over many years on the complex relationships of pregnancy and tuberculosis have been presented, and certain new theories have been advanced to explain the findings. It is my hope that these theories will be tested by other observers, and that in this way some advances may be made not only in the management of pregnancy in the tuberculous woman but also in the knowledge of the biochemical factors concerned in resistance to tuberculosis.

SUMMARY

A study has been made of 718 pregnancies in 534 women.

Survival-rates for the groups with active pulmonary tuberculosis do not suggest that the effect of pregnancy on the group as a whole is adverse. If the course of the disease is in some cases influenced unfavourably, this is more than counterbalanced by the cases in which pregnancy influences the course of the disease favourably.

Pregnancy in a woman with quiescent pulmonary tuberculosis can be considered to add very little to the risk of reactivation to which any quiescent case is subject. The two periods of pregnancy at which factors arising from pregnancy may exert an unfavourable influence are the first four months and the time immediately following parturition.

The prognosis in active pulmonary tuberculosis where spontaneous abortion occurs seems to be appreciably better than in the group with active tuberculosis where the pregnancy goes on full term.

The theory propounded to explain these findings is that the influence of chorionic gonadotropin is potentially adverse, while the influence of œstrogen is potentially favourable, in patients with coexisting pulmonary tuberculosis either active or quiescent. The danger in the first four months is due to the high levels of gonadotropin in the body-fluids. The danger at parturition arises from the sudden withdrawal of œstrogen from the body-fluids, the gonadotropin level being still very much above preconception levels, while the patient is in the phase of puerperal debility.

If this theory is correct, it seems that little advantage is to be expected from terminating pregnancy in a woman with active pulmonary tuberculosis after the end of the first trimester. Similarly the modern practice of administering gonadotropic substances to counteract a tendency to early abortion may in a woman with tuberculosis carry some risk of reactivating the tuberculous disease.

". . . The *internist* . . . is recognizable by his preoccupied look, as a man wrestling with difficulties. His gait is steady but careful, as if he were treading on treacherous ground. In fact he is always walking from one riddle into another. What is wheezing in that chest? What is growling in that abdomen? He looks, he listens, he percusses, he palpates, and he still does not know. Considering every organ as a potential villain, he suspects the liver, distrusts the pancreas, questions the stomach and has his doubts about the kidneys. To him the abdominal wall is a wailing wall, and the human body a walking box of Pandora containing all possible ills . . . The *surgeon* cuts more of a figure. His walk is brisk, and his carriage buoyant. Obviously, his path is clear. He exudes optimism and radiates confidence. Being a thorough man, he leaves no stone unturned, so that the world has few secrets for him, and his patients none. He invariably goes to the bottom of the question, no matter how deep, and if he comes out bloody he holds the answer in his hand. The burden of accumulated uncertainty that weighs on the shoulders of the internist never bends the surgeon's erect structure."—Dr. PAUL DUFAULT, *New Engl. J. Med.* March 23, p. 429.

PENICILLIN IN THE TREATMENT OF UNCOMPLICATED GONORRHŒA

A. J. KING

THE prompt effect of penicillin in limiting spread of infection and preventing complications in cases of uncomplicated gonorrhœa has led to its general acceptance not only as a major advance in methods of treatment, which it certainly is, but as a panacea, which it certainly is not. The beneficial effects have been so obvious and so striking as to convince many that gonorrhœa is no longer a public-health problem and no longer merits consideration as a subject for research.

Two statements from authoritative sources in recent years illustrate this. The report of the first session of the Expert Committee on Venereal Diseases of the World Health Organisation Interim Commission (1949), makes the following reference to gonorrhœa: "Antibiotic therapy appears to have transformed gonorrhœa from a disease of great chronicity with frequent recurrences, with great tendency to troublesome complications and protracted disability, to an infection readily amenable to treatment and with almost complete freedom from complications or tendency to relapse." Mahoney (1947) giving his views on research on venereal diseases expresses himself as so satisfied with the modern treatment of gonorrhœa that "the only intensive investigative effort which appears to be warranted from the public health point of view lies in the field of prophylaxis."

The present investigation brings evidence which is not conclusive but suggests that some successes of treatment with penicillin may be more apparent than real.

WHAT IS A CURE?

Gonorrhœa is a disease which tends to infectious latency; so cure is always difficult to determine with certainty. In most of the reports of series treated with penicillin, the decision as to cure has been reached after brief observation, lasting a few days or a few weeks, supported by a few negative smears and cultures from the prostatic secretion in the male and from urethra and cervix in the female.

Such criteria of cure are unreliable, we believe, because longer clinical observation and further microscopical and cultural tests reveal a number of additional failures of treatment. Microscopical and cultural tests are most important; but it is not safe to depend on these alone, for, like so many laboratory tests, they suffer from inherent difficulties of technique. A positive cultural test from a reliable laboratory cannot be ignored; but a negative test from the same source may well be of *no significance.*

In males with uncomplicated gonococcal urethritis treated with penicillin the gross signs of urethritis nearly always clear very quickly. If the patient is then examined during the day, after holding urine for two or three hours, he seems quite well and is free from signs. If, however, he attends in the early morning, after holding urine for eight hours or more, there will often be slight secretion at the meatus, smears from which show polymorphonuclear leucocytes and, in an occasional case, gonococci. The urine may show pus or pus threads. These signs of residual infection often persist, and there may be also excess of polymorphonuclear leucocytes in the prostatic secretion. In some of these cases relapse occurs with purulent urethritis, and gonococci may be found again. Such relapses are usually attributed to reinfection, whether the history supports this view or not; for it is part of the moral judgment which even the physician passes upon the unfortunate patient with venereal disease that he is rarely considered capable of speaking the truth.

In most female patients treated with penicillin the gonococcus rapidly disappears from the secretions and any symptoms due to gonorrhœa are relieved. Signs of infection of the cervix, however, are apt to persist, and erosion and mucopurulent discharge may remain indefinitely. In some cases the gonococcus persists or reappears, and in an occasional case it continues to do so in spite of massive doses of penicillin.

The question of relapse or reinfection cannot be settled finally, because the two conditions are indistinguishable. The same difficulty arises in assessing the results of treatment of early syphilis by rapid methods, including penicillin. There is no means of distinguishing between infectious relapse and reinfection, and in the many careful and conservative studies on this subject it has therefore been customary to include all these cases as relapses, so weighting the evidence against the drug under investigation. There is a strong case for equal care and conservatism in assessing the results of treatment of gonorrhœa with penicillin. We suggest, therefore, that all cases of gonorrhœa in which gonococci are found again within three months of the time of treatment should be regarded as relapses. There are cases in which relapse seems to have occurred more than three months after treatment; but the rule we have suggested would probably cover most of the doubtful cases.

The hypothesis sometimes advanced to explain the reappearance of gonococci is that there are foci of infection to which the penicillin in the blood-stream does not penetrate. There is little or no evidence for or against this explanation; for these patients seldom show clinical evidence of abscess formation or any other complication. Alternatively the infection is presumed to be "penicillin-resistant." Bacteriologically this implies that the gonococci in subculture should prove to be resistant to penicillin in vitro. This test might give useful information; but, for various technical reasons concerned with the difficulty of isolating the organism in pure culture, we have not yet succeeded in applying the test to our own cases as a routine procedure. At the same time it may be questioned whether the reactions of the gonococcus in the test-tube are a real index of its probable behaviour in vitro. The incalculable factor of tissue immunity in the host remains. In the days when gonococci were found to be "sulphonamide-resistant" there was little correlation between the findings in vivo and vitro.

SOME RESULTS

In support of these views we present an analysis of 1788 cases of fresh acute uncomplicated gonorrhœa in the male and 481 cases of similar infection in the female. All the females and 805 of the males had been infected for the first time. All were treated with a routine course of 150,000 units of sodium penicillin in water, consisting of five doses of 30,000 units given at intervals of two hours.

Males

Of the 1788 men, 341 did not attend for observation and nothing is known of their subsequent history, leaving 1447 in whom some assessment could be attempted; 403 of these patients attended for three months or more and 1044 for less than three months.

1. Of those who remained under observation 94 (6·4%) are considered to be immediate failures of treatment because gross signs of infection persisted or reappeared within two weeks or because acute complications of the

embedding of the ovum and placental development. Browne et al. (1939) found low gonadotropin levels in early abortion, whereas Jeffcoate (1932) found that some cases of inevitable abortion were associated with an excess of œstrogen in the body-fluids. If these findings are correct, and spontaneous abortion in a substantial proportion of cases is associated with either a deficiency of gonadotropin or an excess of œstrogen, the favourable survival-rates in tuberculosis associated with spontaneous abortion can be explained by the hormonic theory outlined above, in that the very factor which is inimical to the pregnancy exerts a favourable influence on the tuberculosis.

It appears incontrovertible that the first four months of pregnancy and the weeks immediately succeeding parturition are the only periods in pregnancy during which any special risk regarding tuberculosis exists. The theory has been advanced that these potential dangers are due to the fact that excess of gonadotropin is an adverse factor and excess of œstrogen a favourable factor, the sudden withdrawal of which, in the presence of a high gonadotropin level, may exert an unfavourable influence, particularly during the period of debility in the puerperium. If this is accepted, it is difficult to justify the induction of abortion once the phase of gonadotropic domination has passed and the phase of œstrogen domination has begun. Perhaps the phase of œstrogenic domination is responsible for those cases in which pregnancy leads to improvement in the tuberculosis. In practice this means that little advantage is to be expected from terminating a pregnancy later than the 14th week. This has been my own view for many years, but mainly on the grounds that with each week after the first trimester the risks of abortion increase while the advantages do not seem to increase. Now there seems to be a more rational scientific reason for restricting induction of abortion to cases in which it is indicated in the first trimester. It also seems that, if pregnancy must be terminated, the earlier in the first trimester at which it can be terminated the greater is the probable advantage.

The modern practice of administering gonadotropic substances to counteract a tendency to early abortion is one which also requires very careful consideration if the patient shows evidence of past or present tuberculosis. On the other hand, the exhibition of œstrogenic substances, such as stilbœstrol immediately after parturition where suppression of lactation is desired, may be beneficial to the tuberculous woman by lessening the impact of the sudden fall in œstrogen level which normally takes place at this time. It is a common practice, and has for long been my own practice and the practice of my obstetrical colleagues, to suppress lactation in this way in active tuberculosis where suckling would be dangerous to the baby. It may well be that this action, which has in the past been dictated by the welfare of the baby, has also an advantage for the mother which more than counterbalances the loss of the tonic effects of lactation on involution of the uterus. Here is a point which merits investigation: would administration of œstrogen for a period after parturition in women with active tuberculosis assist in countering the special dangers of the puerperium?

CONCLUSION

Clinical observations over many years on the complex relationships of pregnancy and tuberculosis have been presented, and certain new theories have been advanced to explain the findings. It is my hope that these theories will be tested by other observers, and that in this way some advances may be made not only in the management of pregnancy in the tuberculous woman but also in the knowledge of the biochemical factors concerned in resistance to tuberculosis.

SUMMARY

A study has been made of 718 pregnancies in 534 women.

Survival-rates for the groups with active pulmonary tuberculosis do not suggest that the effect of pregnancy on the group as a whole is adverse. If the course of the disease is in some cases influenced unfavourably, this is more than counterbalanced by the cases in which pregnancy influences the course of the disease favourably.

Pregnancy in a woman with quiescent pulmonary tuberculosis can be considered to add very little to the risk of reactivation to which any quiescent case is subject. The two periods of pregnancy at which factors arising from pregnancy may exert an unfavourable influence are the first four months and the time immediately following parturition.

The prognosis in active pulmonary tuberculosis where spontaneous abortion occurs seems to be appreciably better than in the group with active tuberculosis where the pregnancy goes on full term.

The theory propounded to explain these findings is that the influence of chorionic gonadotropin is potentially adverse, while the influence of œstrogen is potentially favourable, in patients with coexisting pulmonary tuberculosis either active or quiescent. The danger in the first four months is due to the high levels of gonadotropin in the body-fluids. The danger at parturition arises from the sudden withdrawal of œstrogen from the body-fluids, the gonadotropin level being still very much above preconception levels, while the patient is in the phase of puerperal debility.

If this theory is correct, it seems that little advantage is to be expected from terminating pregnancy in a woman with active pulmonary tuberculosis after the end of the first trimester. Similarly the modern practice of administering gonadotropic substances to counteract a tendency to early abortion may in a woman with tuberculosis carry some risk of reactivating the tuberculous disease.

PENICILLIN IN THE TREATMENT OF UNCOMPLICATED GONORRHŒA

A. J. King
M.B. Lond., F.R.C.S.

F. R. Curtis
M.Sc., M.B. Leeds

C. S. Nicol
M.D. Lond., M.R.C.P.

From the Department of Venereal Diseases, London Hospital (Whitechapel Clinic)

The prompt effect of penicillin in limiting spread of infection and preventing complications in cases of uncomplicated gonorrhœa has led to its general acceptance not only as a major advance in methods of treatment, which it certainly is, but as a panacea, which it certainly is not. The beneficial effects have been so obvious and so striking as to convince many that gonorrhœa is no longer a public-health problem and no longer merits consideration as a subject for research.

Two statements from authoritative sources in recent years illustrate this. The report of the first session of the Expert Committee on Venereal Diseases of the World Health Organisation Interim Commission (1949), makes the following reference to gonorrhœa: "Antibiotic therapy appears to have transformed gonorrhœa from a disease of great chronicity with frequent recurrences, with great tendency to troublesome complications and protracted disability, to an infection readily amenable to treatment and with almost complete freedom from complications or tendency to relapse." Mahoney (1947) giving his views on research on venereal diseases expresses himself as so satisfied with the modern treatment of gonorrhœa that "the only intensive investigative effort which appears to be warranted from the public health point of view lies in the field of prophylaxis."

The present investigation brings evidence which is not conclusive but suggests that some successes of treatment with penicillin may be more apparent than real.

WHAT IS A CURE?

Gonorrhœa is a disease which tends to infectious latency; so cure is always difficult to determine with certainty. In most of the reports of series treated with penicillin, the decision as to cure has been reached after brief observation, lasting a few days or a few weeks, supported by a few negative smears and cultures from the prostatic secretion in the male and from urethra and cervix in the female.

Such criteria of cure are unreliable, we believe, because longer clinical observation and further microscopical and cultural tests reveal a number of additional failures of treatment. Microscopical and cultural tests are most important; but it is not safe to depend on these alone, for, like so many laboratory tests, they suffer from inherent difficulties of technique. A positive cultural test from a reliable laboratory cannot be ignored; but a negative test from the same source may well be of no significance.

In males with uncomplicated gonococcal urethritis treated with penicillin the gross signs of urethritis nearly always clear very quickly. If the patient is then examined during the day, after holding urine for two or three hours, he seems quite well and is free from signs. If, however, he attends in the early morning, after holding urine for eight hours or more, there will often be slight secretion at the meatus, smears from which show polymorphonuclear leucocytes and, in an occasional case, gonococci. The urine may show pus or pus threads. These signs of residual infection often persist, and there may be also excess of polymorphonuclear leucocytes in the prostatic secretion. In some of these cases relapse occurs with purulent urethritis, and gonococci may be found again. Such relapses are usually attributed to reinfection, whether the history supports this view or not; for it is part of the moral judgment which even the physician passes upon the unfortunate patient with venereal disease that he is rarely considered capable of speaking the truth.

In most female patients treated with penicillin the *gonococcus* rapidly disappears from the secretions and any symptoms due to gonorrhœa are relieved. Signs of infection of the cervix, however, are apt to persist, and erosion and mucopurulent discharge may remain indefinitely. In some cases the gonococcus persists or reappears, and in an occasional case it continues to do so in spite of massive doses of penicillin.

The question of relapse or reinfection cannot be settled finally, because the two conditions are indistinguishable. The same difficulty arises in assessing the results of treatment of early syphilis by rapid methods, including penicillin. There is no means of distinguishing between infectious relapse and reinfection, and in the many careful and conservative studies on this subject it has therefore been customary to include all these cases as relapses, so weighting the evidence against the drug under investigation. There is a strong case for equal care and conservatism in assessing the results of treatment of gonorrhœa with penicillin. We suggest, therefore, that all cases of gonorrhœa in which gonococci are found again within three months of the time of treatment should be regarded as relapses. There are cases in which relapse seems to have occurred more than three months after treatment; but the rule we have suggested would probably cover most of the doubtful cases.

The hypothesis sometimes advanced to explain the reappearance of gonococci is that there are foci of infection to which the penicillin in the blood-stream does not penetrate. There is little or no evidence for or against this explanation; for these patients seldom show clinical evidence of abscess formation or any other complication. Alternatively the infection is presumed to be "penicillin-resistant." Bacteriologically this implies that the gonococci in subculture should prove to be resistant to penicillin in vitro. This test might give useful information; but, for various technical reasons concerned with the difficulty of isolating the organism in pure culture, we have not yet succeeded in applying the test to our own cases as a routine procedure. At the same time it may be questioned whether the reactions of the gonococcus in the test-tube are a real index of its probable behaviour in vitro. The incalculable factor of tissue immunity in the host remains. In the days when gonococci were found to be "sulphonamide-resistant" there was little correlation between the findings in vivo and vitro.

SOME RESULTS

In support of these views we present an analysis of 1788 cases of fresh acute uncomplicated gonorrhœa in the male and 481 cases of similar infection in the female. All the females and 805 of the males had been infected for the first time. All were treated with a routine course of 150,000 units of sodium penicillin in water, consisting of five doses of 30,000 units given at intervals of two hours.

Males

Of the 1788 men, 341 did not attend for observation and nothing is known of their subsequent history, leaving 1447 in whom some assessment could be attempted; 403 of these patients attended for three months or more and 1044 for less than three months.

1. Of those who remained under observation 94 (6·4%) are considered to be immediate failures of treatment because gross signs of infection persisted or reappeared within two weeks or because acute complications of the

disease supervened after treatment. Of these 94, 48 showed signs of urethritis, with gonococci persisting in the urethral secretion in 25, and 34 had gross pyuria without urethral discharge. Further courses of penicillin abolished the signs of infection in almost all these cases. Epididymitis appeared in 5 patients, arthritis in 5, and infection of a Cowper's gland in 2, within five weeks after treatment with penicillin.

2. During observation after apparent cure no fewer than 276 (19·1%) patients developed acute purulent urethritis from two to thirteen weeks after treatment, and 216 (14·9%) of them showed gonococci in the secretions. Of this group of 216 patients, 116 admitted further sexual intercourse while the remaining 100 denied it.

3. A third group of 270 patients (18·6%) who were free from symptoms showed evidence of residual infection in the prostate or seminal vesicles. In 27 of these, abnormalities of prostate or seminal vesicles were detected by the examining finger in the rectum and confirmed by microscopic tests; 6 showed gonococci in prostatic smears and in 19 cases cultures from prostatovesicular material yielded gonococci; and 218 patients without detectable abnormality on rectal examination showed gross excess of leucocytes in secretion obtained by massaging prostate and seminal vesicles. Some of these findings may be interpreted as due to previous infections. Of the 270 patients, 141 had a history of previous gonorrhœa or urethritis while 129 gave no such history. If we discard those patients with a history of previous infection, the percentage showing evidence of residual infection becomes 8·9 instead of 18·6. The total failures revealed by follow-up, including relapses and those with residual infection, amount to 546 (37·7%) or, after eliminating those patients with history of previous infection, 405 (27·9%).

Females

Of 481 women, 49 did not attend for observation, which leaves 432 in whom assessment was possible: 265 of these remained under observation for three months or more and 167 for less than three months. Most of these women continued to show some signs of infection both clinically and by the presence of numbers of polymorphonuclear leucocytes in stained smears, especially from the cervix. Immediate failure of treatment was assessed by the continuing presence of the gonococcus or by its reappearance within two weeks. This happened in 15 cases (3·5%). Disappearance of gonococci followed further injections of penicillin. In 56 (13·4%) of the 417 cases left after deducting the 15 immediate failures, the gonococcus reappeared during the later period of observation—in 25 during the first month, in 8 during the second month, in 11 during the third month, and in 12 others subsequently. Further sexual intercourse was admitted by 27 and denied by 29. Among those who relapsed during the period of observation 11 developed signs of salpingitis and 3 bartholinitis.

COMMENT

The whole group of cases, therefore, male and female, showed an immediate response to penicillin which was just as satisfactory as general experience had led us to expect. Nevertheless there was strong evidence that in a number of cases the infection was suppressed rather than cured. The continuing evidence of a persisting low-grade infection, combined with clinical or bacteriological relapse in a considerable proportion of cases, points unmistakeably, in our opinion, to the conclusion that the results of the treatment of gonorrhœa with penicillin are less satisfactory than is generally believed.

We are aware, of course, that many observers would be prepared to describe as reinfections the cases we have classified as relapses. But according to calculations submitted by Sutherland (1950) the chances of acquiring a venereal infection by non-marital sexual intercourse must be very small in relation to the number of exposures: in other words the probabilities are against the assertion that the cases we have classified as relapses are in reality new cases of gonorrhœa. Furthermore, such is the insensitiveness of present methods of isolating or demonstrating the presence of the gonococcus in human secretions and tissues that it seems wiser to weight the evidence against a method of treatment, by including as relapses some possible reinfections, than to encourage a false conception of the value of the treatment by refusing to admit the fact that relapses occur. Although, for everyday practical purposes, some venereologists may be led to assume that all men are liars, such an assumption is not a very scientific standpoint from which to study a disorder like gonorrhœa, in which our knowledge is so small and our methods of isolation of the causative organism in the chronic stage of the disease are so inadequate.

SUMMARY

1. The results of treatment of 2269 patients with acute uncomplicated gonorrhœa, including 1788 males and 481 females, are presented.

2. All were treated with 150,000 units of sodium penicillin in water, in five doses each of 30,000 units given at intervals of two hours.

3. Assessment is restricted to 1447 males and 432 females who attended for tests for cure.

4. Of these, 94 men (6·4%) and 15 women (3·5%) were regarded as immediate failures of treatment because the gonococcus persisted in the secretions or reappeared within two weeks, or because they developed acute complications of the infection after penicillin had been given. In nearly all these cases the gross signs of infection cleared with additional injections of penicillin.

5. Of the remaining men, 276 (19·1%) developed acute purulent urethritis during observation after apparent cure. Of these, 216 (14·9%) showed gonococci in the secretions in the second attack. A further 270 (18·6%) showed evidence of residual infection in the genital tract, detected by the examining finger in 27 and by microscopic or cultural test in 243. Thus in the male patients the total "late" failures, obtained by adding "relapses" to those with residual infections amount to 546 (37·7%) or, after eliminating those patients with history of previous genital infection, 405 (27·9%).

6. Of the remaining women, 56 (13·4%) showed the gonococcus in genital secretions during observation two weeks or more after treatment.

7. The opinion is expressed that reinfection does not account for the major proportion of these failures. Relapse and reinfection are indistinguishable, and for scientific accuracy all such cases, whether relapses or reinfections, which occur during three months' observation after treatment should be classed as failures. If this method of assessment be accepted, penicillin is less effective in the treatment of acute uncomplicated gonorrhœa than it is generally reported to be.

AN attempt has been made to evaluate the usefulness of certain steroids in the treatment of active rheumatoid arthritis. This therapeutic trial was conducted in two parts; in the first, steroid therapy alone was given; in the second, the same steroids, and also deoxycortone acetate, were combined with ascorbic acid.

I. Steroid Therapy Alone

In view of the possibility that the enzymal systems of the body might be able to convert other members of the cyclo-penteno-phenanthrene ring system into 11-oxysteroids, and since there were other indications for their therapeutic trial, it was decided to treat comparable groups of cases of active rheumatoid arthritis with large doses of methyl testosterone, testosterone propionate, ethinyl œstradiol, progesterone, and chorionic gonadotrophin ('Pregnyl').

These particular steroids were selected for the following reasons. Progesterone has been considered a possible causative factor in the remission of rheumatoid arthritis during pregnancy. Since this work started, it has also been shown that in active rheumatoid arthritis the amount of pregnanediol excreted after administration of progesterone is double the normal; and this suggests some abnormality in steroid metabolism in this disease.[13] Chorionic gonadotrophin has been claimed to benefit rheumatoid arthritis.[12] Testosterone has proved of value in the treatment of the refractory anæmia of hypopituitarism,[17] and it was hoped that it might at least help the refractory anæmia accompanying active rheumatoid arthritis. For many years œstrogens have been a popular remedy for the climacteric type of rheumatoid arthritis.

METHODS AND DEFINITIONS

All cases had routine physical treatment. In view of the number of series that were being followed, it was felt that the groups would act as controls to each other, and that any steroid of definite value would stand out from the remainder when the time for assessment arrived.

Each case was assessed periodically during and after treatment. The clinical observations, which are independent of laboratory findings, are summarised below. Table I presents a complete summary of the clinical changes (including weight), laboratory findings, and "activity indices" in all the cases.

The "activity index" represents an attempt to give a numerical value to the activity of the disease. The index is derived from 4 factors—change in weight, erythrocyte-sedimentation rate (E.S.R.), hæmoglobin levels (Hb), and degree of pain at rest. These are graded on a three-point scale as follows:

Weight.—Stationary or increasing, 0. Slight loss (1–4 lb.), 1. Gross loss (more than 4 lb.), 2.

E.S.R. (Westergren, after 1 hr.).—0–15 mm., 0. 16–40 mm., 1. Over 40 mm., 2.

Hb.—80% or over, 0. 65–79%, 1. 64% or below, 2.

Rest pain.—Absent, 0. Slight, 1. Severe, 2.

The activity index obtained by adding up the appropriate figures is arbitrary; changes in weight and inconstancies of the E.S.R. may obviously be misleading. Many patients feel that they have improved as a result of a stay in hospital, though laboratory findings may suggest that their condition is unchanged or has even deteriorated. For such reasons there are discrepancies in some of the present cases between the clinical assessment and the activity index.

CLINICAL ASSESSMENT

Ethinyl Œstradiol (cases 1–9)

Of the 9 patients, 7 were women and 2 men.

Dosage and Side-effects.—Each of these 9 patients received 0·01 mg. of ethinyl œstradiol thrice daily. In 3 cases this treatment was discontinued owing to bleeding per vaginam—in cases 7 and 8 after two weeks, and in case 9 after nine days—and treatment was later continued with methyl testosterone.

Results.—Early definite improvement was noted in 3 cases (1–3). Case 3, a man, continued this treatment for six months, by the end of which there was pain, swelling, and tenderness of the breasts; the improvement was very marked in the first three months and was maintained for the whole period.

There was slight improvement in 2 cases (4 and 5).

No change was detected in 1 case (6).

In 3 cases (7–9) where treatment had to be discontinued within two weeks the patients' condition deteriorated.

Methyl Testosterone (cases 10–21)

Of the 12 patients, 10 were women and 2 men; 3 of the women (cases 19–21) had previously been treated with ethinyl œstradiol (see above).

Dosage and Side-effects.—All the 12 patients received 5 mg. t.d.s. for three months except:

Case 13, in which 5 mg. t.d.s. was given for five weeks and three days, and 10 mg. t.d.s. for a further eight weeks.

Case 15, in which 5 mg. t.d.s. was given for six weeks and 10 mg. t.d.s. for a further six weeks.

Case 19, in which 5 mg. t.d.s. was given for three weeks, and 10 mg. t.d.s. for a further nine weeks and three days.

In cases 15 and 19, both female, the voice deepened after ten weeks' and eleven weeks' treatment.

Pustular acne developed in 2 cases (20 and 21), both female. The first of these patients developed a mild eruption after six weeks' treatment. After a further four weeks, treatment was stopped because of worsening of the acne and lack of improvement in the rheumatic condition. In the second case, severe acne appeared after four weeks' treatment; the dose was gradually reduced by the patient's own doctor and finally stopped after six weeks' treatment. The patient's rheumatic condition improved quite considerably. Both these patients had previously had ethinyl œstradiol, which had to be discontinued because of bleeding per vaginam.

In 1 case (17), a female, œdema of the ankles developed rapidly a week after treatment was started. Since there was no gross arthritis of the ankles and no evidence of a cardiac or renal lesion, it was thought that the treatment might be responsible, and this was discontinued. The patient, who was an outpatient, failed to report again.

Results.—Fairly definite improvement took place in 3 cases (15, 19, and 21).

Fairly definite improvement in general health with no change or deterioration in the joint condition was observed in 6 cases (11–13 and 16–18).

No change was noted in 2 cases (10 and 20).

One case (14) deteriorated.

Testosterone Propionate (cases 30–36)

Of the 7 patients, 3 were women and 4 men. Case 35 had previously had a course of methyl testosterone (see case 10), completed two weeks before testosterone propionate was begun. Case 33 was suffering from ankylosing spondylitis with pronounced anæmia.

Dosage and Side-effects.—4 patients (cases 30–32 and 36) had 25 mg. intramuscularly thrice weekly for three weeks; 2 patients (cases 33 and 34) had 50 mg. thrice weekly for one week, then 100 mg. thrice weekly for the second week, and 100 mg. daily for the third week. One patient (case 35) had 50 mg. thrice weekly for one week, then 100 mg. thrice weekly for the second week, 100 mg. daily for three days, and 300 mg. daily for one week.

One patient (case 31) said that her appetite increased considerably at her midday meal on the day of each injection (given in the morning), but not at her evening meal or on the days when she had no injection.

Results.—Fairly definite improvement took place in 3 cases (31, 33, and 34).

Slight improvement took place in 1 case (30).

No change was noted in 3 cases (32, 35, and 36).

Pregnyl (cases 22–29, 44)

Of the 9 patients 7 were women and 2 men. Case 27 had previously had a course of progesterone (see case 41), completed two weeks before pregnyl was begun

Dosage and Side-effects.—7 patients (cases 22–28) had 500 units intramuscularly thrice weekly for three weeks. 2 patients (cases 29 and 44) had 2000 units intramuscularly daily for one week.

Cases 24 and 25 had some headache after the first and second injections only; and case 29 had an exacerbation of the pains in all her joints six hours after each injection and lasting six hours, this being most troublesome after the first three injections. This patient did appear to improve when ascorbic acid was added (table II, case 10).

Results.—Fairly definite improvement in general health, without change in the joint symptoms, was observed in 3 cases (22, 24, and 25).

No change was noted in 3 cases (23, 27, and 28).

The condition of 2 patients (cases 26 and 29) deteriorated.

Definite clinical improvement, both in general health and arthritic symptoms, with gain in weight but with deterioration in blood condition, was observed in 1 case (44).

† Wintrobe. ‡ Westergren. * = ankylosing spondylitis. − = deterioration. 0 = no change. + = slight improvement. + + = well-marked improvement. Sev. = severe. Sl. = slight.

Progesterone (cases 37–43)

Of the 7 patients, 4 were women and 3 men.

Dosage and Side-effects.—2 patient (cases 37 and 38) had 25 mg. intramuscularly daily for three weeks; and 5 (cases 39–43) had 50 mg. daily for one week and then 100 mg. daily for a further two weeks.

Result.—There were no untoward reactions.

Fairly definite improvement took place in 1 case (38).

Slight improvement was observed in 3 cases (39, 42, and 43).

No change was noted in 2 cases (37 and 40).

The condition of 1 patient (case 41) deteriorated.

BLOOD-VOLUMES

On 26 occasions blood-volumes were estimated, by a modification of the method of Gregerson,[5] before and after treatment. Notable alterations were found in only 3 cases—2 women treated with pregnyl and 1 man treated with progesterone (cases 24, 25, and 39). In these 3 cases the blood-volumes after treatment showed increases of 71%, 40%, and 44%; the hæmatocrit values remained virtually the same. These cases showed no particular clinical response.

CONCLUSIONS

It will be seen that of the 9 cases taking ethinyl œstradiol, only 6 completed the course; and of these 6, 3 showed some definite, and 2 slight, improvement. The 3 who stopped treatment, because of menorrhagia, were definitely worse as regards their arthritis. Of the 12 taking methyl testosterone, 3 showed improvement in the joint condition. Of 7 taking testosterone propionate, 3 showed moderate improvement in their arthritis, and 1 was slightly improved. Of the 7 cases taking progesterone, 4 said their joints were slightly easier. Pregnyl produced improvement in the arthritis in only 1 of 9 cases.

About two-thirds of all the patients felt better in general health. None of the preparations used had any significant effect on anæmia.

Allowing for the vagaries of the disease and the benefit usually derived from rest, encouragement, and physical treatment in hospital, we are doubtful whether these steroids played any significant part in the therapeutic results. These findings are in conformity with those of Alexander and Duthie[1] in 5 cases with progesterone.

II. Steroids with Ascorbic Acid

When the therapeutic value of any of these steroids by itself proved far from convincing, it was decided to try the effect of these same preparations with the addition of ascorbic acid, and to compare the results with those obtained with deoxycortone acetate and ascorbic acid, using the method of Lewin and Wassén.[10] At the same time direct eosinophil-counts and urinary uric-acid creatinine ratios were estimated to see whether there was any corticoid effect; and the percentage of ascorbic acid in the urine was also noted in case the extent of ascorbic-acid saturation played any part in the variability of results.

TABLE II—EFFECT OF VARIOUS STEROIDS, USED IN CONJUNCTION WITH ASCORBIC ACID.

Case no.	Treatment (with ascorbic acid)	Sex and age	Clinical change after 1st and 2nd injections										E.S.R.† (mm. 1 hr.)		Hb (g. per 100 ml.)		Eosinophils per c.mm.		Uric-acid creatinine ratio		% Ascorbic acid excd. in urine after 1st inj.

* = ankylosing spondylitis. † = corrected Wintrobe. — = deterioration. 0 = no change. + = slight improvement. + + = well-marked improvement.

might be responsible, and this was discontinued. The patient, who was an outpatient, failed to report again.

Results.—Fairly definite improvement took place in 3 cases (15, 19, and 21).

Fairly definite improvement in general health with no change or deterioration in the joint condition was observed in 6 cases (11–13 and 16–18).

No change was noted in 2 cases (10 and 20).

One case (14) deteriorated.

Testosterone Propionate (cases 30–36)

Of the 7 patients, 3 were women and 4 men. Case 35 had previously had a course of methyl testosterone (see case 10), completed two weeks before testosterone propionate was begun. Case 33 was suffering from ankylosing spondylitis with pronounced anæmia.

Dosage and Side-effects.—4 patients (cases 30–32 and 36) had 25 mg. intramuscularly thrice weekly for three weeks; 2 patients (cases 33 and 34) had 50 mg. thrice weekly for one week, then 100 mg. thrice weekly for the second week, and 100 mg. daily for the third week. One patient (case 35) had 50 mg. thrice weekly for one week, then 100 mg. thrice weekly for the second week, 100 mg. daily for three days, and 300 mg. daily for one week.

One patient (case 31) said that her appetite increased considerably at her midday meal on the day of each injection (given in the morning), but not at her evening meal or on the days when she had no injection.

Results.—Fairly definite improvement took place in 3 cases (31, 33, and 34).

Slight improvement took place in 1 case (30).

No change was noted in 3 cases (32, 35, and 36).

Pregnyl (cases 22–29, 44)

Of the 9 patients 7 were women and 2 men. Case 27 had previously had a course of progesterone (see case 41), completed two weeks before pregnyl was begun

Dosage and Side-effects.—7 patients (cases 22–28) had 500 units intramuscularly thrice weekly for three weeks. 2 patients (cases 29 and 44) had 2000 units intramuscularly daily for one week.

Cases 24 and 25 had some headache after the first and second injections only; and case 29 had an exacerbation of the pains in all her joints six hours after each injection and lasting six hours, this being most troublesome after the first three injections. This patient did appear to improve when ascorbic acid was added (table II, case 10).

Results.—Fairly definite improvement in general health, without change in the joint symptoms, was observed in 3 cases (22, 24, and 25).

No change was noted in 3 cases (23, 27, and 28).

The condition of 2 patients (cases 26 and 29) deteriorated.

Definite clinical improvement, both in general health and arthritic symptoms, with gain in weight but with deterioration in blood condition, was observed in 1 case (44).

† Wintrobe. ‡ Westergren. * = ankylosing spondylitis. – = deterioration. 0 = no change. + = slight improvement. + + = well-marked improvement. Sev. = severe. Sl. = slight.

was given). This improvement has now been maintained for three weeks.

In case 13 there was considerable improvement in joint pain two hours after the first combined injection, and the pain was relieved completely four hours later. This improvement has now been maintained for three weeks.

Cases 10 and 11 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 37 and 23).

Testosterone Propionate and Ascorbic Acid (cases 14–17)

Of the 4 patients, 2 were women and 2 men.

Dosage and Side-effects.—3 patients (cases 15–17) had 300 mg. testosterone propionate intramuscularly daily for three days, and on each of the latter two days had 1 g. ascorbic acid intravenously. Case 14 had been treated with testosterone propionate for over three weeks (case 35 of table I) before ascorbic acid was given intravenously in addition.

Results.—Case 14 showed no significant change.

In case 15 there was very slight insignificant increase in stiffness of both knee-joints shortly after each injection.

In case 16 the joint pains improved two hours after the first combined injection, and this improvement lasted for five days. There was no significant change after the second injection.

In case 17 joint pains improved two hours after the first combined injection, and stiffness diminished three hours after the second.

This improvement was the best the patient had noted for seven months. Both pain and stiffness returned twenty-four hours after the second injection.

Cases 15, 16, and 17 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 24, 28, and 34 respectively).

Progesterone and Ascorbic Acid (cases 18–21)

Of the 4 patients, 3 were women and 1 a man.

Dosage and Side-effects.—3 patients (cases 18, 20, and 21) had 100 mg. progesterone intramuscularly daily for three days, and on each of the latter two days 1 g. ascorbic acid intravenously. Case 19 had been treated with progesterone for three weeks (case 43 of table I) before ascorbic acid was given intravenously in addition. In view of the improvement noted in this case (see below) a further course of progesterone and ascorbic acid was administered, but on this occasion for a three-day period only.

Results.—Case 20 showed no significant change.

In case 18 there was much improvement in joint pains and some improvement of stiffness about three and a half hours after the first combined injection. The patient felt that the movements of her joints were freer, and her steps on walking were bigger. Shortly after the second injection, however, the joint pains, stiffness, and degree of movement all were worse. During that day and for the next few days the patient felt generally unwell.

In case 19 there was no change after the first combined injection, but three hours after the second injection joint pains were less, and there was improvement in the ability to make a fist and in the power of grip of both hands. No further improvement followed the second course of injections a week later. The improvement gained has now been maintained for four weeks.

In case 21, pain and stiffness of the right shoulder increased one hour after the first injection, and pain and stiffness of the left shoulder increased five hours after the injection. This exacerbation gradually settled during the next two days, the second injection apparently having no effect. Thirty-six hours after the second injection pains increased in the right knee and fingers of both hands.

Cases 19, 20, and 21 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 30, 36, and 35).

Deoxycortone and Ascorbic Acid (cases 22–41)

Of the 20 patients, 12 were women and 8 men.

Dosage and Side-effects.—All the patients had 5 mg. deoxycortone acetate intramuscularly followed immediately by 1 g. ascorbic acid intravenously on two successive days. In 2 patients (cases 24 and 25) the ascorbic acid had to be given intramuscularly and in 1 patient (case 31), where the first ascorbic acid was given intravenously, the second was given intramuscularly.

Cases 22 and 26 had previously been treated with ethinyl œstradiol and ascorbic acid. Cases 25, 27, and 29 had previously been treated with methyl testosterone and ascorbic acid. Cases 23 and 37 had previously been treated with pregnyl and ascorbic acid. Cases 24, 28, and 34 had previously been treated with testosterone propionate and ascorbic acid. Cases 30, 35, and 36 had previously been treated with progesterone and ascorbic acid. The remaining patients had had no previous endocrine therapy.

Case 33 was the only patient in the series suffering from ankylosing spondylitis.

Results.—No change whatever resulted in 13 patients (cases 22, 23, 25, 28, 29, 30, 31, 34, 35, 38, 39, 40, and 41).

In 2 cases (24 and 27) the patients noticed that stiffness was less than usual when they got up on the morning of the day after the first combined injection. The stiffness returned to its usual state later during that day and apparently was unaffected by the second injection. The stiffness was not improved on the morning of the day after the latter injection.

In case 36 there was very slight improvement in pains and stiffness two hours after each combined injection The improvement after the second lasted thirty-six hours.

In case 37 there was slight improvement of stiffness of the left shoulder-joint three hours after the second combined injection. There was no change after the first.

In case 26 there was an increase in general stiffness immediately after the first combined injection. This persisted for three days and apparently was unaffected by the second injection.

In case 32 there was well-marked relief of pain in the right knee-joint immediately after the first combined injection; and this relief has now been maintained for five weeks. Stiffness of other joints was increased one hour after the first injection, but much relieved one hour after the second.

In case 33 (ankylosing spondylitis) there was much improvement in the stiffness and degree of movement of the whole spine, especially rotation of the cervical spine, immediately after the first combined injection. Improvement continued during the following week.

In only cases 32 and 33 did the improvement appear to be in any way significant.

LABORATORY FINDINGS

It will be seen from table II that in no case was there a decrease of circulating eosinophils or increase in the urinary uric-acid creatinine ratio to suggest any corticoid effect.

There was no correlation between the saturation with ascorbic acid and the therapeutic result; the route of administration of ascorbic acid showed no correlation with the saturation or the therapeutic effect.

CONCLUSIONS

From the case-reports and tables it may be seen that if patients' statements that they improved are accepted, A preliminary report of these findings is being published in view of the extremely diverse reports now appearing in the medical press.[2–4, 6–9, 11, 14–16]

METHODS

Altogether, 21 cases have been treated with the preparations already tried, but with the addition of ascorbic acid. In the case of the steroids given by injection (testosterone propionate, progesterone, and pregnyl) the technique was to give an injection of the steroid one day and then the steroid and ascorbic acid together on the two succeeding days, the ascorbic acid being given immediately after the steroid. Ethinyl œstradiol and methyl testosterone were taken by mouth for at least a week before, as well as during, the ascorbic-acid administration.

For comparison, 20 cases were treated with deoxycortone acetate and ascorbic acid on two successive days.[10] Deoxycortone acetate (5 mg.) was injected intramuscularly into the lateral aspect of the thigh and ascorbic acid (1 g.) was injected intravenously immediately afterwards. In a few cases, ascorbic acid had to be given intramuscularly because flexed elbows or poor veins made intravenous administration difficult.

All patients were assessed clinically by one observer (L. M.) from the point of view of general health and pain, stiffness, movement, and swelling of affected joints. They were also questioned about functional ability—including ability to dress, shave, brush the hair, use a knife and fork, and walk.

Sedimentation-rates, hæmoglobin, and eosinophil-counts were estimated before treatment and again five hours after the last injection of ascorbic acid. Uric-acid creatinine ratios were estimated on 24-hour urine specimens before treatment; and for the 24 hours immediately after the last ascorbic-acid injection.

Urinary ascorbic-acid excretion was observed in the five hours after the first injection of ascorbic acid (1 g.); in a normally saturated person at least 40% of the dose should be excreted in this time.

RESULTS

The laboratory findings and a summary of clinical observations are given in table II.

In many cases no therapeutic benefit was apparent. Only those cases in which improvement may conceivably have resulted are quoted in any detail. The remainder received no benefit whatever, and in fact 5 patients actually complained of increased joint pain after the injections.

Ethinyl Œstradiol and Ascorbic Acid (cases 1–4)

Of the 4 patients, 1 was a woman and 3 men.

Dosage and Side-effects.—All had 0 05 mg. ethinyl œstradiol by mouth thrice daily for ten days, and on the ninth and also the tenth day had 1·0 g. ascorbic acid injected intravenously.

Results.—In case 1, the joint pains increased two hours after the first injection of ascorbic acid. The pain was unaffected by the second injection, but twenty-four hours afterwards it improved.

In case 2, immediately after each injection, the pain in the right ankle improved and walking was much easier; on each occasion this improvement lasted 1–1½ hours.

In case 3, joint pain was eased two hours after the first injection, but aggravated one hour after the second injection.

In case 4, there was improvement in joint pains two hours after the first injection, this improvement lasting twelve hours. The pain also improved one hour after the second injection, for thirty-six hours. After the second injection, movement (ability to make a fist and power of grip) was better and swelling of the metacarpophalangeal joints was somewhat reduced. The return of pain was associated with a return of swelling and diminished movement.

Cases 1 and 2 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 22 and 26).

Methyl Testosterone and Ascorbic Acid (cases 5–8)

Of the 4 patients, 2 were women and 2 men.

Dosage and Side-effects.—3 patients (cases 5, 7, and 9) had 10 mg. of methyl testosterone thrice daily by mouth for ten days, and on the ninth and also the tenth days had 1 g. ascorbic acid injected intravenously. Case 6 had been treated with methyl testosterone for three months (case 19 of table I) before ascorbic acid was given—intramuscularly in this case. Case 8 was an outpatient.

Results.—In case 5, there was an improvement in the joint pains two hours after the first injection and an hour after the second injection, the improvement after the second injection lasting for forty-eight hours.

Case 6 showed no significant change.

In case 7 there was increased pain and stiffness in all joints during the night after the first injection. This improved somewhat on the following morning (before the second injection was given). On the day after the second injection there was an improvement in general health and in the pains and stiffness of all joints.

In case 8 joint pains were less after the first and second injections. After the second injection the improvement lasted for four days, but then the pain became worse than ever before.

Cases 5, 6, and 7 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 27, 25, and 29).

Pregnyl and Ascorbic Acid (cases 9–13)

Of the 5 patients, 3 were women and 2 men.

Dosage and Side-effects.—Cases 9, 11, and 13 had 2000 units of pregnyl intramuscularly daily for three days, and on each of the last two days had 1 g. ascorbic acid (intramuscularly in case 9). Cases 10 and 12 had 2000 units daily for ten days, with ascorbic acid (1 g.) intravenously on the last two days. Both these cases had been fully assessed after one week's daily pregnyl (cases 29 and 44 of table I). In view of the improvement noted in case 10 (see below), a further course of pregnyl and ascorbic acid was given subsequently, but on this occasion the pregnyl was given *for the three-day* period only, as above.

Results.—Cases 9 and 11 showed no significant change; but in case 11 there was a mild gastric disturbance on the day of the first combined injection.

In case 10, on the morning after the first combined injection (and before the second was given) the patient noticed a definite improvement in the extent of movement of her shoulder-joints. She could lift her arms 9 in. above her head, whereas before she could barely touch the top of her head; and she could dress and brush her hair more easily. On the morning after the second injection she found that she could internally rotate the left shoulder more fully, and the pain in all joints was less. The improvement of movement, which has now been maintained for four weeks, is the best she has experienced for two years. When a second course of combined injections was given a week later, there was no further improvement in the movement, but there was an increase of pain one hour after the second injection, easing off after seven hours.

In case 12 there was slight improvement of pain and stiffness of the left hand immediately after the first injection, and an improvement of the pains in the feet on the following morning (before the second injection was given). This improvement has now been maintained for three weeks.

In case 13 there was considerable improvement in joint pain two hours after the first combined injection, and the pain was relieved completely four hours later. This improvement has now been maintained for three weeks.

Cases 10 and 11 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 37 and 23).

Testosterone Propionate and Ascorbic Acid (*cases 14–17*)

Of the 4 patients, 2 were women and 2 men.

Dosage and Side-effects.—3 patients (cases 15–17) had 300 mg. testosterone propionate intramuscularly daily for three days, and on each of the latter two days had 1 g. ascorbic acid intravenously. Case 14 had been treated with testosterone propionate for over three weeks (case 35 of table I) before ascorbic acid was given intravenously in addition.

Results.—Case 14 showed no significant change.

In case 15 there was very slight insignificant increase in stiffness of both knee-joints shortly after each injection.

In case 16 the joint pains improved two hours after the first combined injection, and this improvement lasted for five days. There was no significant change after the second injection.

In case 17 joint pains improved two hours after the first combined injection, and stiffness diminished three hours after the second.

This improvement was the best the patient had noted for seven months. Both pain and stiffness returned twenty-four hours after the second injection.

Cases 15, 16, and 17 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 24, 28, and 34 respectively).

Progesterone and Ascorbic Acid (*cases 18–21*)

Of the 4 patients, 3 were women and 1 a man.

Dosage and Side-effects.—3 patients (cases 18, 20, and 21) had 100 mg. progesterone intramuscularly daily for three days, and on each of the latter two days 1 g. ascorbic acid intravenously. Case 19 had been treated with progesterone for three weeks (case 43 of table I) before ascorbic acid was given intravenously in addition. In view of the improvement noted in this case (see below) a further course of progesterone and ascorbic acid was administered, but on this occasion for a three-day period only.

Results.—Case 20 showed no significant change.

In case 18 there was much improvement in joint pains and some improvement of stiffness about three and a half hours after the first combined injection. The patient felt that the movements of her joints were freer, and her steps on walking were bigger. Shortly after the second injection, however, the joint pains, stiffness, and degree of movement all were worse. During that day and for the next few days the patient felt generally unwell.

In case 19 there was no change after the first combined injection, but three hours after the second injection joint pains were less, and there was improvement in the ability to make a fist and in the power of grip of both hands. No further improvement followed the second course of injections a week later. The improvement gained has now been maintained for four weeks.

In case 21, pain and stiffness of the right shoulder increased one hour after the first injection, and pain and stiffness of the left shoulder increased five hours after the injection. This exacerbation gradually settled during the next two days, the second injection apparently having no effect. Thirty-six hours after the second injection pains increased in the right knee and fingers of both hands.

Cases 19, 20, and 21 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 30, 36, and 35).

Deoxycortone and Ascorbic Acid (*cases 22–41*)

Of the 20 patients, 12 were women and 8 men.

Dosage and Side-effects.—All the patients had 5 mg. deoxycortone acetate intramuscularly followed immediately by 1 g. ascorbic acid intravenously on two successive days. In 2 patients (cases 24 and 25) the ascorbic acid had to be given intramuscularly and in 1 patient (case 31), where the first ascorbic acid was given intravenously, the second was given intramuscularly.

Cases 22 and 26 had previously been treated with ethinyl œstradiol and ascorbic acid. Cases 25, 27, and 29 had previously been treated with methyl testosterone and ascorbic acid. Cases 23 and 37 had previously been treated with pregnyl and ascorbic acid. Cases 24, 28, and 34 had previously been treated with testosterone propionate and ascorbic acid. Cases 30, 35, and 36 had previously been treated with progesterone and ascorbic acid. The remaining patients had had no previous endocrine therapy.

Case 33 was the only patient in the series suffering from ankylosing spondylitis.

Results.—No change whatever resulted in 13 patients (cases 22, 23, 25, 28, 29, 30, 31, 34, 35, 38, 39, 40, and 41).

In 2 cases (24 and 27) the patients noticed that stiffness was less than usual when they got up on the morning of the day after the first combined injection. The stiffness returned to its usual state later during that day and apparently was unaffected by the second injection. The stiffness was not improved on the morning of the day after the latter injection.

In case 36 there was very slight improvement in pains and stiffness two hours after each combined injection The improvement after the second lasted thirty-six hours.

In case 37 there was slight improvement of stiffness of the left shoulder-joint three hours after the second combined injection. There was no change after the first.

In case 26 there was an increase in general stiffness immediately after the first combined injection. This persisted for three days and apparently was unaffected by the second injection.

In case 32 there was well-marked relief of pain in the right knee-joint immediately after the first combined injection; and this relief has now been maintained for five weeks. Stiffness of other joints was increased one hour after the first injection, but much relieved one hour after the second.

In case 33 (ankylosing spondylitis) there was much improvement in the stiffness and degree of movement of the whole spine, especially rotation of the cervical spine, immediately after the first combined injection. Improvement continued during the following week.

In only cases 32 and 33 did the improvement appear to be in any way significant.

LABORATORY FINDINGS

It will be seen from table II that in no case was there a decrease of circulating eosinophils or increase in the urinary uric-acid creatinine ratio to suggest any corticoid effect.

There was no correlation between the saturation with ascorbic acid and the therapeutic result; the route of administration of ascorbic acid showed no correlation with the saturation or the therapeutic effect.

CONCLUSIONS

From the case-reports and tables it may be seen that if patients' statements that they improved are accepted, A preliminary report of these findings is being published in view of the extremely diverse reports now appearing in the medical press.[2–4 6–9 11 14–16]

METHODS

Altogether, 21 cases have been treated with the preparations already tried, but with the addition of ascorbic acid. In the case of the steroids given by injection (testosterone propionate, progesterone, and pregnyl) the technique was to give an injection of the steroid one day and then the steroid and ascorbic acid together on the two succeeding days, the ascorbic acid being given immediately after the steroid. Ethinyl œstradiol and methyl testosterone were taken by mouth for at least a week before, as well as during, the ascorbic-acid administration.

For comparison, 20 cases were treated with deoxycortone acetate and ascorbic acid on two successive days.[10] Deoxycortone acetate (5 mg.) was injected intramuscularly into the lateral aspect of the thigh and ascorbic acid (1 g.) was injected intravenously immediately afterwards. In a few cases, ascorbic acid had to be given intramuscularly because flexed elbows or poor veins made intravenous administration difficult.

All patients were assessed clinically by one observer (L. M.) from the point of view of general health and pain, stiffness, movement, and swelling of affected joints. They were also questioned about functional ability—including ability to dress, shave, brush the hair, use a knife and fork, and walk.

Sedimentation-rates, hæmoglobin, and eosinophil-counts were estimated before treatment and again five hours after the last injection of ascorbic acid. Uric-acid creatinine ratios were estimated on 24-hour urine specimens before treatment; and for the 24 hours immediately after the last ascorbic-acid injection.

Urinary ascorbic-acid excretion was observed in the five hours after the first injection of ascorbic acid (1 g.); in a normally saturated person at least 40% of the dose should be excreted in this time.

RESULTS

The laboratory findings and a summary of clinical observations are given in table II.

In many cases no therapeutic benefit was apparent. Only those cases in which improvement may conceivably have resulted are quoted in any detail. The remainder received no benefit whatever, and in fact 5 patients actually complained of increased joint pain after the injections.

Ethinyl Œstradiol and Ascorbic Acid (*cases 1–4*)

Of the 4 patients, 1 was a woman and 3 men.

Dosage and Side-effects.—All had 0·05 mg. ethinyl œstradiol by mouth thrice daily for ten days, and on the ninth and also the tenth day had 1·0 g. ascorbic acid injected intravenously.

Results.—In case 1, the joint pains increased two hours after the first injection of ascorbic acid. The pain was unaffected by the second injection, but twenty-four hours afterwards it improved.

In case 2, immediately after each injection, the pain in the right ankle improved and walking was much easier; on each occasion this improvement lasted 1–1½ hours.

In case 3, joint pain was eased two hours after the first injection, but aggravated one hour after the second injection.

In case 4, there was improvement in joint pains two hours after the first injection, this improvement lasting twelve hours. The pain also improved one hour after the second injection, for thirty-six hours. After the second injection, movement (ability to make a fist and power of grip) was better and swelling of the metacarpophalangeal joints was somewhat reduced. The return of pain was associated with a return of swelling and diminished movement.

Cases 1 and 2 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 22 and 26).

Methyl Testosterone and Ascorbic Acid (*cases 5–8*)

Of the 4 patients, 2 were women and 2 men.

Dosage and Side-effects.—3 patients (cases 5, 7, and 9) had 10 mg. of methyl testosterone thrice daily by mouth for ten days, and on the ninth and also the tenth days had 1 g. ascorbic acid injected intravenously. Case 6 had been treated with methyl testosterone for three months (case 19 of table I) before ascorbic acid was given—intramuscularly in this case. Case 8 was an outpatient.

Results.—In case 5, there was an improvement in the joint pains two hours after the first injection and an hour after the second injection, the improvement after the second injection lasting for forty-eight hours.

Case 6 showed no significant change.

In case 7 there was increased pain and stiffness in all joints during the night after the first injection. This improved somewhat on the following morning (before the second injection was given). On the day after the second injection there was an improvement in general health and in the pains and stiffness of all joints.

In case 8 joint pains were less after the first and second injections. After the second injection the improvement lasted for four days, but then the pain became worse than ever before.

Cases 5, 6, and 7 were subsequently treated with deoxycortone acetate and ascorbic acid (cases 27, 25, and 29).

Pregnyl and Ascorbic Acid (*cases 9–13*)

Of the 5 patients, 3 were women and 2 men.

Dosage and Side-effects.—Cases 9, 11, and 13 had 2000 units of pregnyl intramuscularly daily for three days, and on each of the last two days had 1 g. ascorbic acid (intramuscularly in case 9). Cases 10 and 12 had 2000 units daily for ten days, with ascorbic acid (1 g.) intravenously on the last two days. Both these cases had been fully assessed after one week's daily pregnyl (cases 29 and 44 of table I). In view of the improvement noted in case 10 (see below), a further course of pregnyl and ascorbic acid was given subsequently, but on this occasion the pregnyl was given for the three-day period only, as above.

Results.—Cases 9 and 11 showed no significant change; but in case 11 there was a mild gastric disturbance on the day of the first combined injection.

In case 10, on the morning after the first combined injection (and before the second was given) the patient noticed a definite improvement in the extent of movement of her shoulder-joints. She could lift her arms 9 in. above her head, whereas before she could barely touch the top of her head; and she could dress and brush her hair more easily. On the morning after the second injection she found that she could internally rotate the left shoulder more fully, and the pain in all joints was less. The improvement of movement, which has now been maintained for four weeks, is the best she has experienced for two years. When a second course of combined injections was given a week later, there was no further improvement in the movement, but there was an increase of pain one hour after the second injection, easing off after seven hours.

In case 12 there was slight improvement of pain and stiffness of the left hand immediately after the first injection, and an improvement of the pains in the feet on the following morning (before the second injection

FINDINGS IN ILLUSTRATIVE CASES

Case 1.—A female clerk, aged 47, whose symptoms started in 1944. The injections were given on Dec. 19, 1949.

Joint	Diameters of joints (cm.) before and after injections						
	Before	1 hr.	2 hr.	3 hr.	4 hr.	5 hr.	6 hr.
Rt wrist ..	15·7	15·7	15·7	15·5	15·5	15·5	15·5
Lt wrist ..	14·7	14·6	14·4	14·4	14·4	14·4	14·4
Rt ankle ..	24·0	24 0	23·8	23·8	23 7	23·7	23·7
Rt knee ..	37·0	37·0	37·0	37·0	37·0	37·2	37·2

Finding	Before	2 hr.	4 hr.	6 hr.
E.S.R. (mm. in 1st hr.)	33	47·0	41·0	42·0
Plasma viscosity (sec.)	38	34·6	35·0	35·0

The patient said she felt no improvement in the joints, but a sense of mental exhilaration began shortly after the injection and lasted, gradually diminishing in intensity, for about three days. Since she left the wards she has been attending the rheumatic clinic weekly and has been having, by her own request, weekly injections of deoxycortone and vitamin C. She says that her joints are not improved but that she greatly appreciates the "mental uplift" which lasts for some days after each injection.

Case 3.—A housewife, aged 43, whose symptoms started n 1943. The injections were given on Jan. 12, 1950.

Joint	Diameters of joints (cm.) before and after injections						
	Before	1 hr.	2 hr.	3 hr.	4 hr.	5 hr.	6 hr.
Rt wrist ..	18·0	18·0	18·0	18·0	17·8	18 0	17·8

Finding	Before	2 hr.	4 hr.	6 hr.
E.S.R. (mm. in 1st hr.)	9·0	32 0	38 0	43·0
Plasma viscosity (sec.)	34·8	29·0	31 6	..

There was no increase in the range of movements. The patient said that the joints were not improved but that she felt somewhat exhilarated for two days after the injections. Since leaving the wards she has been attending the rheumatic clinic weekly and has been given, at her own request, weekly injections of deoxycortone and vitamin C.

Case 4.—A housewife, aged 40, whose symptoms started in 1943. The injections were given on Jan. 12, 1950.

Joint	Diameters of joints (cm.) before and after injections						
	Before	1 hr.	2 hr.	3 hr.	4 hr.	5 hr.	6 hr.
Rt wrist ..	18·5	18·5	18 2	18·2	18·3	18·3	18·3
Lt wrist ..	18·5	18 6	18 7	18·6	18·6	18·6	18·6
Rt ankle ..	26 5	26·3	26·3	26 3	26·3	26·3	26·3

Finding	Before	2 hr.	4 hr.	6 hr.
E.S.R. (mm. in 1st hr.)	46 0	40 0	46 0	46·0
Plasma viscosity (sec.)	32 0	33 5	32 8	32 4

There was no increase in the range of movement of the affected joints, and the patient did not feel improved.

CONTROLS

As will be seen from the table, 2 patients (cases 1 and 14) reported some symptomatic benefit from the treatment. At subsequent injections, unknown to them, sterile physiological saline solution was given in place of the deoxycortone and vitamin C. The subjective results were as follows:

Case no.	After injections of deoxycortone and vitamin C			After injections of saline solution		
	Feb. 21	March 14	March 21	Feb. 28	March 7	March 16
14	Improved	Greatly improved	Improved	Improved	Improved	Improved
1	Improved	Improved	Improved	Improved	Greatly improved	Improved

DISCUSSION

We feel that some comments are justifiable concerning the difficulties of assessing improvement in rheumatoid arthritis and the interpretation of these and other reported results.

In rheumatoid arthritis spontaneous remissions are common. These are usually subjective, and are of very variable duration, lasting from a few hours to several months or years. Most patients, indeed, say they have good days and bad days, often associated with changes in the weather.

The patient's performance is limited not only by the damage to, and the pain in, affected joints but also by his or her willingness to move the joints. Thus we have found that aspirin or any other anodyne (e.g., physeptone) will improve the patient's performance without affecting the disease in other respects. It must also be common experience to find greater improvement, with any treatment, in the more suggestible and coöperative patients.

Patients with rheumatoid arthritis may be divided, broadly, into two groups: (1) those who accept their disability as incurable, with the attitude of mind aptly described by the phrase "What can't be changed must be tholed"; and (2) those who refuse to yield to their affliction and struggle on with their work and recreations in spite of their disability. We have further found that symptomatic improvement with any form of treatment is extremely common—at least temporarily—in the second group.

The present investigation has not convinced us that deoxycortone and vitamin C, in the recommended doses, are of any value in the treatment of rheumatoid arthritis. The technique we have followed does not, we think, leave us open to the criticisms directed by Le Vay and Loxton (1949, 1950) at previous work yielding negative results.

Finally, we feel that in view of the wide differences of opinion regarding the value of this treatment, speculation about the mechanism of its beneficial action is, to say the least, premature.

We wish to thank Dr. J. W. Macfarlane for his interest and criticism, and for so willingly placing beds at our disposal.

Spies, T. D., Stone, R. E., de Maeyer, E., Niedermeier, W. (1949) *Ibid*, p. 1219.

there was some betterment in 2 out of 4 cases treated with ascorbic acid and ethinyl œstradiol; in 2 out of 4 treated with methyl testosterone; in 3 out of 5 treated with pregnyl; in 2 out of 4 treated with testosterone propionate; in 2 out of 4 treated with progesterone; and in only 3 out of 20 treated with deoxycortone acetate.

A more critical examination of the results shows that case 4 on ethinyl œstradiol, case 10 on pregnyl, case 17 on testosterone propionate, cases 18 and 19 on progesterone and ascorbic acid, and cases 32 and 33 on deoxycortone acetate can be accepted as showing some definite temporary improvement.

In only 4 out of 42 cases was any pronounced improvement maintained for more than forty-eight hours, and it is definitely felt that the promiscuous use of deoxycortone acetate and ascorbic acid as a method of treatment is to be deprecated at present.

The carefully controlled investigation of the use of other steroids together with ascorbic acid, however, merits further attention.

We should like to thank Dr. Hubert Gibson, Dr. Ruth Pearson, Dr. E. Bene, and the sisters and nursing staff of the hospital for their help.

MEDICAL REGISTRAR

GLASGOW ROYAL INFIRMARY

SINCE Lewin and Wassén's original note (1949) on the treatment of rheumatoid arthritis with deoxycortone and vitamin C many papers have appeared on this subject. Some observers (Hallberg 1950) report results even more dramatic than those with 'Cortisone.' Others report no benefit from the same treatment (Hartfall and Harris 1949, Kellgren 1949, Lloyd Hart and Starer 1949, Spies et al. 1949)

It is regrettable that the favourable reports have often been based on uncontrolled experiments and that subjective improvement alone has sometimes been accepted as evidence of improvement in the joints. Most rheumatologists will agree that one of the difficulties in treating rheumatoid arthritis lies in the accurate assessment of improvement. The clinical application of Kendall's Compound E (cortisone) has been most strictly investigated by Hench and his colleagues (1949), due attention being paid to its effect not only on the symptoms of the disease but on the objective signs and range of movements in the affected joints and the erythrocyte-sedimentation rate (E.S.R.); these experiments were also satisfactorily controlled.

This paper records a series of experiments with deoxycortone and vitamin C begun immediately after the publication of Lewin and Wassén's paper and continued until now.

METHODS AND RESULTS

The 17 patients treated were selected as fulfilling the clinical criteria for a diagnosis of rheumatoid arthritis, and in addition all had:

(1) Raised E.S.R.
(2) Negative Wassermann and Kahn reactions.
(3) Negative gonococcal flocculation test.
(4) Normal blood-level of uric acid.
(5) Negative agglutination test for abortus fever.

All the patients volunteered to come into hospital so that they could be kept under proper surveillance. No patient had less than four injections of the drugs.

The method of administration used was the popular one—deoxycortone in an oily solution injected intramuscularly, followed within 10 minutes by an intravenous injection of an aqueous solution of vitamin C. The doses were: deoxycortone 5 mg., and vitamin C 1 g.

The results of treatment in the 17 patients are set out in the accompanying table. More details are given for specimen cases to illustrate the results of the investigations carried out.

SUBJECTIVE AND OBJECTIVE CHANGES AFTER INJECTIONS OF DEOXYCORTONE AND VITAMIN C IN 17 PATIENTS WITH RHEUMATOID ARTHRITIS

Great difficulty was experienced in finding an accurate method of joint measurement. The method ultimately adopted was to ring the skin over the maximum diameter with ink and on each subsequent occasion to apply the tape-measure to this line. Even so, we have found that variations up to 0·5 cm. may arise from experimental error. Consequently, any change in the joint measurements less than 0·5 cm. is not regarded as significant.

The E.S.R. and plasma viscosity were measured at constant temperature in a thermostatically controlled water tank.

on his advice the patient was admitted to the General Hospital. Lumbar puncture again produced normal C.S.F. under normal pressure. A white-cell count of the blood showed 15,000 (63% polymorphs) per c.mm. Blood was taken for culture. The pyrexia and headache continued.

Aug. 13: a few rose spots were seen, and the spleen was thought to be palpable.

Aug. 15: rose spots were still present, and the spleen was definitely palpable. Typhoid bacilli were reported to have been found in the blood-culture. A Widal test was positive: (H) 1/320; (O) 1/120. The patient was transferred back to Ladywell Hospital on the same day.

Aug. 16: the patient's temperature fell in the morning but rose to 103·6°F at 10 P.M. His general condition was not improving, he was toxic, rose spots were present on abdomen and chest, and stools were fluid but not frequent.

Aug. 17: temperature 102·2°F, tongue covered with brown fur, headache complained of, abdomen large, and bowels not opened. Chloramphenicol therapy was started with a loading dose of 4 g.

Aug. 18: temperature 102°F, rumblings in abdomen, bowels not opened. Chloramphenicol 1·5 g. was given twice daily. Rose spots were fading.

Aug. 19: temperature 97°F at 6 A.M., abdomen distended, meteorism, bowels not opened. Flatus tube inserted and saline enema given.

Aug. 20: temperature 100·4°F, complained of abdominal pain, meteorism, bowels not opened.

Aug. 21: bowels opened after an enema, abdomen soft and less distended, temperature 98·6°F, general condition improved, and rose spots almost gone.

Aug. 22: rash faded, temperature normal, no headache, no abdominal pains. Condition improved rapidly from now on.

Aug. 25: the dosage of chloramphenicol was reduced to 1·5 g. twice daily until Aug. 29. It was then reduced to 1 g. daily until Sept. 5, when it was discontinued. The total dosage over twenty days was 41·5 g.

Sept. 12: the patient's fæces still contained typhoid bacilli.

Sept. 30: a week's course of procaine penicillin and sulphadimidine was started. The fæces were negative on Oct. 13, positive on Oct. 17, negative on Oct. 18, 19, and 22, and positive on Oct. 26 and 28. On Oct. 31 a second course of penicillin and sulphadimidine was started. After this course the patient's fæces were negative on six occasions and his urine on three. He was discharged in good health on Nov. 19.

This was a case of severe typhoid with delirium. Chloramphenicol was not given until the seventeenth day of disease. Dosage, after the loading dose, was too small and the doses were spaced too widely—i.e., twelve-hourly—and response was somewhat slow but definite.

Case 2.—A woman, aged 51, had had some ice-cream on Oct. 28 and begun to have a headache and general malaise on Nov. 7 and shivering on Nov. 11.

On admission on Nov. 15 her temperature was 102·6°F, and pulse-rate 96. The patient was flushed, toxic, and felt weary. Her tongue was thickly coated, and she was constipated and had a slight cough. Nothing abnormal was found in her lungs or heart. Her spleen was just palpable, but there was no rash. A Widal test was positive for *S. typhi* (H) 1/640, (O) 1/160, and for *S. paratyphi-B* (O) 1/80.

Treatment.—Chloramphenicol 4 g. was given as an initial dose, followed by 2 g. eight-hourly (6 g. daily), and a simple enema was given.

Nov. 16: a blood-culture was negative, but *S. typhi* was isolated from the fæces. The patient's temperature was 102·6°F and her pulse-rate 96. Her general condition was unchanged, and she was flushed and toxic, but did not complain of anything. Later she became delirious and got out of bed. Her temperature was 102·8°F at 10 P.M. She was given tepid sponging and a sedative.

Nov. 17: temperature 102·6°F, pulse-rate 96, bowels opened, urine passed. The patient was toxic and mentally confused. A few rose spots were seen on her abdomen. Her tongue was dry. The dosage of chloramphenicol was increased to 2 g. six-hourly (8 g. daily).

Nov. 18: temperature 100·2°F, pulse-rate 80. The patient was mentally much clearer. Bowels not opened, but they opened later after an enema of glycerin and magnesium sulphate.

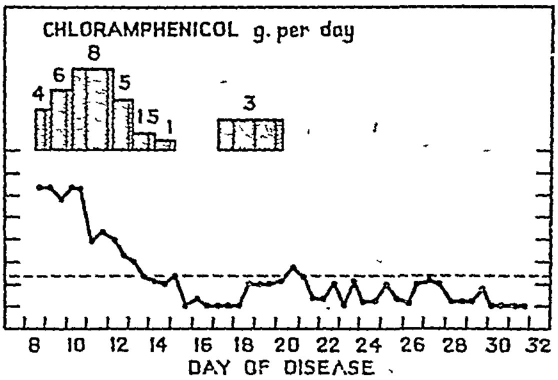

Fig. 2—Temperature chart of case 2.

Nov. 19: temperature 100°F, pulse-rate 80. Condition improved, but tongue dry and coated. More fluids ordered. The dosage of chloramphenicol was reduced to 1 g. six-hourly (4 g. daily).

Nov. 20: temperature 99°F, pulse-rate 80. Patient's condition much improved, and bowels opened. The dosage of chloramphenicol was reduced to 0·5 g. b.d.

Nov. 21: temperature 98·2°F, pulse-rate 80. Generally much improved, bowels opened, somewhat loose. Patient not complaining of anything.

Nov. 22: chloramphenicol discontinued.

Nov. 24: the patient felt well; temperature 97°F, pulse-rate 80, but bowels loose. Chloramphenicol, 1 g. eight-hourly was given.

Nov. 25: improvement continued.

Nov. 27: chloramphenicol was discontinued. The patient's condition continued to improve rapidly, and on Dec. 8 she was allowed up for a short time.

Dec. 13: the patient's fæces still contained typhoid bacilli; so a week's course of procaine penicillin and sulphadimidine was started. After its completion the patient's fæces were negative on ten occasions, and she was discharged well on Jan. 15.

This was a case of severe typhoid fever in a robust woman of 51, and showed a dramatic response to rather a massive dosage of chloramphenicol.

Case 3.—A man, aged 44, had had some chicken (which he had thought was "high") on Oct. 28. Next day he had had abdominal pain and diarrhœa, which had continued for about three days. On Nov. 4 he had had a shivering attack and felt unwell and vomited. His temperature had been 101·7°F, and he had had a headache.

On admission on Nov. 5 the patient had a temperature of 101·4°F, pulse-rate 110, and respirations 22 a minute. He was a big man, with tongue thickly coated, anorexia, and slight headache. His spleen was impalpable, no rose spots were seen, and his pulse was soft and quick.

Treatment and Progress.—Chloramphenicol 2 g. was given eight-hourly (6 g. daily). Next day there was not much change; the tongue was thickly coated and tremulous on protrusion, and the stools were loose. Owing to his having been inoculated against typhoid fever and having a history suggesting gastro-enteritis, and owing to a shortage of chloram-

TYPHOID FEVER TREATED WITH CHLORAMPHENICOL

REVIEW OF SIXTEEN CASES

William Edge
M.R.C.S., D.P.H.
MEDICAL SUPERINTENDENT, LADYWELL HOSPITAL, SALFORD

At this hospital 16 patients were treated with chloramphenicol in the second half of 1949, 4 females and 12 males (the higher incidence in males was fortuitous, 14 patients having been infected in a men's club when women were present on a guest night). The youngest patient was a girl of 16, and the oldest a man of 75. The average age was 48: of the 4 females the youngest was aged 16, and the oldest 53, average 40; and of the 12 males the youngest was 34, and the oldest 75, average 51.

Before their admission to hospital the illness had lasted on an average 17 days, shortest 7 days, longest 45 (in a female with a bone abscess). The illness was severe in 2 cases, moderately severe in 6, and mild or on the wane in 8.

Chloramphenicol exerted a radical effect on the illness; the classification and prognosis would have been different without it. No definite scheme of treatment could be followed throughout this series; chloramphenicol was sometimes scarce and had to be reserved for the severer cases, and different suggestions about dosage and duration of treatment were received. The effect of chloramphenicol on the course of pyrexia can be seen from the temperature charts (figs. 1–3), but the clinical improvement and complete transformation in a few days can only be appreciated fully by clinicians who have had previous experience of typhoid fever and have known their own helplessness in the past to affect its protracted course.

There were five relapses, no perforations, and one hæmorrhage (a single tarry stool). All the patients made a good recovery. Diarrhœa was a troublesome symptom in 2 patients, and meteorism was severe in 2.

Diet.—Fluids only were allowed during the stage of fever and toxæmia, but when these abated, a gradually increasing diet was given, regulated to the patients' absorptive capacity.

DOSAGE

The average amount of chloramphenicol given for the main attack was 28·3 g., the smallest 11 g., and the largest 47 g. The largest daily dose was 8 g. Chloramphenicol was given usually eight-hourly, but in 2 cases it was given six-hourly to intensify the effect. In 3 cases a first loading dose of 4 g. was given. The duration of treatment averaged 9·5 days, the shortest course lasting 4 days and the longest 20. Treatment was started on an average on the 18th day of illness, the earliest time being the 7th day and latest the 45th day (the patient with the bone abscess).

RESULTS

The temperature in every case was brought to normal by the 6th day at the latest. In the relapses (which occurred on an average on *the 18th day after the temperature* had reached normal, shortest 11th, longest 23rd) the average amount of chloramphenical given was 12·1 g., smallest 5 g., and largest 18 g. The temperature was brought down to normal at the latest by the 5th day on resumption of treatment with chloramphenicol.

RELAPSES

The impression is gained that chloramphenicol has no effect on the clearance of typhoid bacilli from the fæces; in 8 patients bacilli persisted in the fæces. Nor has chloramphenicol prevented relapses: 5 relapses occurred (the patient who had 47 g. spread over 14 days had a relapse and had to be given 18 g. to cure this). Chloramphenicol may not reach the gall-bladder and the intestinal contents in sufficient concentration, and thus the bacilli may be able to survive treatment with chloramphenicol during the main attack. When the body is again freed from chloramphenicol, the way is open for another invasion by the bacilli from the intestines.

BACTERIAL SENSITIVITY

Dr. G. J. Crawford and Dr. E. Greenwood, of the pathological laboratory, Hope Hospital, who did all the bacteriological investigations in these patients, have tested the sensitivity to chloramphenicol of the bacilli from some of these patients; they found that these were sensitive to a concentration of 2·5 μg. per ml. but insensitive to 1·5 μg. per ml. Chloramphenicol 4 g. given to a patient weighing 13 st. would produce a concentration of 51·6 μg. per ml. on the assumption of complete absorption and diffusion through every part of the body. It thus appears theoretically that this dosage is excessive, but in practice it has been found in other diseases that massive doses have to be given to overcome the infection completely. The latest recommendation is an increased dosage and *prolongation of treatment for* a fortnight.

CLEARING FÆCES

To clear the fæces, we gave a week's course of parenteral penicillin and sulphadimidine by mouth, as reported by Rumball and Moore,[1] except that procaine penicillin was given instead of ordinary penicillin. This course was given to 5 patients, and had to be repeated in 2, whose fæces had not been cleared by the first course. After *this treatment the fæces of all the patients so treated* were negative on at least six occasions and the urine on three.

ILLUSTRATIVE CASES

Case 1.—A man, aged 34, was admitted on Aug. 8 as a case of suspected meningitis, which had started with headache on Aug. 1. The patient had continued at his work until Aug. 5. On Aug. 6 he had had shivering, vomiting, and sleepiness, and on Aug. 7 he had become delirious.

On admission the patient complained of severe headache and had a temperature of 100·4°F, some head retraction, and nuchal stiffness. Kernig's test was negative on both sides. There was no rash. The tongue was coated with brownish fur, and the patient was delirious at times. Photophobia was severe; the pupils were equal and reacted to light. Cerebration was somewhat slow, and the patient vomited soon after admission. Lumbar puncture produced 10 ml. of clear cerebrospinal fluid (C.S.F.) under increased pressure and containing albumin. The blood-pressure was 148/70.

Treatment.—Intramuscular penicillin 200,000 units was given six-hourly, and in the evening morphine gr. 1/4 was given for restlessness.

Progress.—Next day the patient had a severe headache and was restless, with temperature 101·4°F. Lumbar puncture produced 30 ml. of clear C.S.F. showing nothing abnormal. A neurologist provisionally diagnosed virus meningitis, and

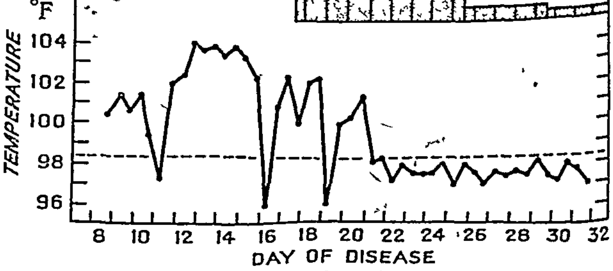

Fig. 1—Temperature chart of case 1.

[1] Rumball, C. A., Moore, L. G. *Brit. med. J.* 1949, i, 615.

yet another possibility : there might be a local deficiency of prothrombin in the capillaries of the actual lesion only. Some such condition might be explained by the hypothesis put forward by Howell (1941) who considered that prothrombin and fibrinogen might be constantly formed and consumed in the blood, leading to the formation of fibrin, which might provide nourishment or protection for the cells of the capillary walls. Hallam (1930), considering acrocyanosis, which he classified with chilblains, suggested that some unknown factor might render a person susceptible to cold, with a resulting destruction of the endothelium of the peripheral capillaries. A deficiency of prothrombin (Howell's theory) might then produce the effects suggested by Hallam. If such a local defect was present, blood leaving the chilblain capillaries would be so diluted on returning to the general circulation as to leave the systemic prothrombin level and that of the general capillary system unimpaired.

The next step, therefore, was to estimate the prothrombin-time in capillary blood taken from the chilblain itself. This was done in case 6, but again the result was normal.

The coming of spring then ended this investigation.

Therapeutic Results

In the third and present series of cases studied there were 3 failures with vitamin-K therapy. In the same way that the experimental investigation had led to a consideration of local capillary defects in the lesions themselves, so these were also considered in an attempt to explain and overcome these failures. The first step was to consider whether some other deficiency leading to capillary defects might not also be present. According to Bicknell and Prestcott (1945) lack of vitamin P leads to decreased capillary resistance. Vitamin P was therefore given with vitamin K in one of the resistant cases (case 1) but with no benefit.

The next speculation was whether impaired circulation might not impede the correct utilisation of prothrombin in the affected areas. With this in mind, nicotinic acid was given to case 1 for its vasodilatory effect. No improvement resulted from nicotinic acid either alone or in combination with vitamin K. Another vasodilator, 'Padutin,' was then tried, in combination with vitamin K, but again without benefit. Padutin had no beneficial effect in 2 further cases.

Winter having now drawn to a close, it had been found impossible to relieve these 3 patients of their chilblains, though all the other cases had responded to vitamin K alone. Perhaps some parallel may be found in those cases of hæmorrhagic disease of the newborn which do not respond to vitamin K and for which no satisfactory explanation has been found. Possibly Owren's factor V may have some bearing on this problem. Owren (1947) described a case of hæmorrhagic diathesis with considerable hypoprothrombinæmia (estimated by Quick's method) which did not respond to vitamin K, whereas factor V, isolated from normal plasma, restored the blood-coagulability to normal. Other cases have also been described as having increased prothrombin-times and not responding to vitamin K (Butt et al. 1948).

ILLUSTRATIVE CASE-RECORDS

Case 1.—A married woman, aged 45, had had severe ulcerated chilblains every winter for as long as she could remember. She had "spent a fortune" trying to cure them, without success. She was seen in October, when the lesions were just beginning to appear on her fingers. She was given synthetic vitamin K 20 mg. t.d.s. by mouth. A week later there was no change and the toes were now also affected. A further week later they were much worse, and she was given synthetic vitamin K 10 mg. by intramuscular injection twice, with a three-day interval between injections. This was in addition to continued oral medication. There was slight improvement, but this coincided with milder weather. The patient continued with this oral dosage until the following January (three months), with no change apart from fluctuations with the weather. The prothrombin-time was found to be 19 seconds, compared to a normal control of 20 seconds. The patient was next given synthetic vitamin P ('Hesperidin') 150 mg. t.d.s. in addition to vitamin K. There was no improvement after two weeks. Both were then omitted and nicotinamide 50 mg. t.d.s. substituted. There was no improvement after nine days, and the nicotinamide was superseded by nicotinic acid 50 mg. t.d.s. for ten days, with slight improvement. This was continued a further eleven days with the addition of synthetic vitamin K, as before, with no improvement at all, the weather having become colder. Spring then intervened without any improvement in this patient's chilblains during the six months from October to March.

Case 2.—A married woman, aged 50, had had chilblains every winter all her life. She was seen in November, when the lesions were just appearing. The prothrombin-time was 19 seconds, compared to a normal control of 12 seconds. The patient was given synthetic vitamin K 20 mg. t.d.s. by mouth, and a fortnight later the chilblains had completely disappeared. The prothrombin-time was then 13 seconds, with the normal control 13 seconds. The patient remained on this dosage for two months, with no recurrence of chilblains ; and it was then reduced to 20 mg. b.d. for three weeks, with the resulting reappearance of mild chilblains. These rapidly cleared when the doses were given t.d.s. again. For the further two winter months the patient remained clear of chilblains on this dosage, making a total of five months during which she experienced complete relief from chilblains.

Case 3.—A stout matron had severe ulcerated chilblains every winter on hands, toes, and heels. In November these were completely abolished with vitamin K. This was then omitted, with return of the lesions in January, the prothrombin-time then being 11 seconds (control 12 seconds). Further synthetic vitamin-K therapy (20 mg. t.d.s. by mouth) again removed these, and the patient remained clear of chilblains for the remainder of the winter on a reduced dose of 20 mg. b.d.

Case 4.—A woman, aged 30, developed moderately severe chilblains on her heels and toes nearly every winter. In November she was given synthetic vitamin K 20 mg. t.d.s. by mouth, with complete cure of the chilblains. This dosage was continued for two months with no recurrence. The patient was now pregnant and, having some vomiting, omitted the tablets, and the chilblains recurred two weeks later. The prothrombin-time was then 13 seconds (control 12 seconds). When vitamin K was given as before, there was no further recurrence of chilblains during the next two months.

Case 5.—An elderly hypertensive spinster took synthetic vitamin K 20 mg. b.d. by mouth for the relief of her chilblains. This was completely successful and enabled her to continue her employment as a shop assistant, whereas previously her cracked and swollen fingers had prevented her from doing so. This was the state of affairs during December and January. In February she was persuaded to omit the tablets, so that the chilblains might recur and the prothrombin-time be estimated. Both of these events happened, and the prothrombin-time was found to be 10 seconds (control 10 seconds). The patient then resumed her synthetic vitamin-K tablets and continued until the end of March, with no trouble from chilblains.

Case 6.—A young married woman had severe chilblains on her toes and hands every winter, but only when the weather was very cold. In the last cold spell of the present winter, while her chilblains were acute, her capillary prothrombin-time was found to be 35 seconds (control 35 seconds). The capillary prothrombin-time of blood from the lesion itself was also normal, compared to the control.

SUMMARY AND CONCLUSIONS

Two parallel investigations have been made into the experimental and clinical effects of vitamin K in chilblains. The limitations of general practice and this country's climate provided only 26 cases for study. The prothrombin-times of 16 of these were estimated, but in only one was there a slight deviation from normal in the acute stage of chilblains. It is considered that there is no alteration in the systemic prothrombin-time in phenicol, the patient was taken off chloramphenicol and put on sulphaguanidine 2 g. eight-hourly and 'Sulphatriad' 1 g. six-hourly.

Nov. 7: the fæces were green, the patient's temperature was 100°F in the morning and 102·2°F in the evening, and he complained of pain in the left side of the chest on taking a breath, but nothing abnormal was detected.

Nov. 8: the patient's temperature fell to 97°F, and he seemed to be somewhat improved.

Nov. 9: the fæces contained typhoid bacilli; so a course of chloramphenicol 1·75 g. eight-hourly (5·25 g. daily) was started, and the other drugs were discontinued. In the evening the pulse-rate was 120, the tongue was coated, the stools were somewhat loose, and the heart had a tick-tack rhythm.

Nov. 11: pyrexia continuing, the patient was put on intramuscular penicillin 1,000,000 units eight-hourly and sulphatriad 1 g. six-hourly.

Nov. 12: the patient felt weary, and was put on 'Eschatin' 1 ml. b.d. Rose spots were seen on the flanks of the abdomen, the spleen was palpable, and the blood-pressure was 105/50. The patient was given 20 ml. of 50% glucose solution intravenously.

Nov. 14: penicillin was discontinued.

Nov. 16: the patient had perspired freely in the night, and now felt better, his temperature having dropped at last.

Nov. 17: chloramphenicol was discontinued after a total dosage of 42·75 g. had been given.

Dec. 9: the patient was allowed up for half an hour.

Dec. 10: he vomited twice, and his tongue was again thickly coated, his temperature was 101°F in the evening, and he felt heavy and weary and had lost his appetite.

Dec. 11: the patient's temperature was 102°F, and his tongue was coated and tremulous on protrusion. A blood-culture grew typhoid bacilli. A course of chloramphenicol 1·5 g. eight-hourly (4·5 g. daily) was started, and was followed by gradual improvement over the next two days.

Dec. 13: the patient's temperature became normal again.

Dec. 14: the dosage of chloramphenicol was changed to 0·5 g. eight-hourly (1·5 g. daily).

Dec. 16: chloramphenicol was discontinued, a total dosage of 14·5 g. having been given for the relapse.

Dec. 31: the patient was discharged after an uneventful convalescence.

The response to the resumed treatment with chloramphenicol was not so quick as in the other cases; possibly the giving of chloramphenicol for one day had made the bacilli more resistant to it. The relapse occurred the day after patient had been allowed up; possibly he got up too early.

CHILBLAINS AND PROTHROMBIN LEVELS

David Wheatley
M.A., M.B. Camb.
GENERAL PRACTITIONER

> "If 'twere a kibe,
> 'Twould put me to my slipper."
> —*The Tempest*, Act II, Sc. 1.

SEVERAL of the minor ailments which burden the practitioner during the winter months might be described as reactions of the human organism to cold. One of the commonest of these is chilblains, which affected 50% of the A.T.S. personnel investigated by Winner and Cooper-Willis (1946) and are sometimes highly disabling. Opinion seems to be unanimous about the nature of the lesions and that the precipitating cause is cold (MacKenna 1937, Roxburgh 1947, &c.). As regards treatment, however, there is a great diversity of remedies, which fact, as Dowling (1948) remarks, is but proof of their ineffectiveness. Gourlay (1948) has reviewed many of them.

Some of the remedies are directed against the symptoms, but others, such as calcium and vitamin D, are intended to "improve" the circulation. Most of the latter are based on Wright's (1897) finding of diminished blood-coagulability in chilblains, which finding was subsequently disproved by Hallam (1930), who demonstrated normal coagulation-times in patients with chilblains. Percival and Stewart (1924) had already demonstrated a normal blood-calcium level in patients with chilblains and the absence of any beneficial results on raising it with 'Para-thormone.' Nicotinic acid has been advocated by Gourlay (1948), but the only effect it has seems to be a widespread, non-specific, and transient vasodilatation.

The fundamental defects present in chilblains are, according to MacKenna (1937), defective peripheral circulation, increased capillary permeability, and diminished blood-coagulation, but, as already mentioned, there is no proof of the last. Roxburgh (1947) lists only the circulatory changes, consisting of dilatation of minute vessels and small veins and constriction of arterioles. In hypoprothrombinæmia MacKenna's three defects are also present, but the diminution in blood-prothrombin may not necessarily be sufficient to affect coagulation-time. It was felt, however, that these facts constituted as good a reason for vitamin-K therapy in chilblains as for the many remedies already tried—and found wanting.

PRELIMINARY INVESTIGATION

As a preliminary study 8 cases were treated with vitamin K (Wheatley 1947). In only 4 of them was complete success obtained, and it was thought probable that vitamin K would have to be relegated to the multitude of other inconclusive remedies for chilblains. However, it was decided to investigate the effect of an increased dosage and protracted treatment.

The number of cases studied in each series is small. This is because the public has lost faith with the medical profession's ability to treat chilblains, so comparatively few people with chilblains consult a doctor.

With the next 10 cases studied there was a 100% success, maintained throughout the winter in those cases which were followed up for this period. *Up to this point* the results had been judged by clinical improvement alone, without controls or hæmatological investigation. At this stage it was felt that some points had emerged:

(1) Administration by mouth was most convenient.

(2) Dosage was fixed at 20 mg. t.d.s.; less was considered insufficient.

(3) There was a time-lag between the start of treatment and the onset of improvement. This was never less than 3 or 4 days, and in a very few cases as long as 2 or 3 weeks. On an average 5–7 days was the most usual.

(4) It was necessary to continue the treatment as long as the cold weather continued. Otherwise the chilblain recurred, again with a similar time-lag, from cessation of treatment.

PRESENT INVESTIGATION

The previous results were considered sufficiently encouraging to stimulate the undertaking of a further investigation designed to test the hypothesis more stringently. This consists of parallel experimental and therapeutic observations on 19 cases studied during the winter of 1948–49.

EXPERIMENTAL RESULTS

In the first stage of the investigation the prothrombin-time was estimated, by Quick's method, in every case of chilblains in the acute stage. In 16 cases studied this was normal compared to a normal control, except in case 2, in which the value was within the normal range but raised in comparison with the control. In case 2 the prothrombin-time returned to normal after vitamin-K therapy, coinciding with the amelioration of the chilblains. It is obvious, however, that generally the prothrombin level of the circulating blood is unaltered in chilblains, and so there was, as yet, no evidence of deficiency of vitamin K in chilblains.

Chilblains, however, are caused by capillary defects in the affected parts. Though it is difficult to conceive that there could be any difference in the prothrombin content of capillary and venous blood, the capillary prothrombin-time was estimated in 2 of the acute cases (see case 6) and found to be normal. There is, however, *Examination of Pus.*—Dr. I. Lominski reported that the pus from the hepatic abscess yielded a heavy growth of penicillin-sensitive *Staph. aureus*. Extended search of the fresh material for *Entamœba histolytica* was unsuccessful. Schistosome eggs were not found in the fresh pus.

Biopsy Findings. (Prof. D. F. Cappell).—The specimen consisted of a small fragment of liver tissue showing hæmorrhage and suppuration resulting from the acute staphylococcal infection. Small tubercle-like foci of reaction were also present, in the centres of two of which were clearly identifiable schistosome eggs. Serial sections were cut to determine whether the ova had lateral spines (*S. mansoni*) or terminal spines (*S. hæmatobium*), but reconstruction was impossible, and this point remains obscure (fig. 2). Two of the foci consisted of a conspicuous reactive cellular zone round the ova, but others were in the process of involution, and one fully hyalinised form was present (fig. 3).

Treatment of Schistosomiasis.—The patient was given intramuscular 'Anthiomaline' (a lithium salt of antimony) 2 ml. thrice weekly for three weeks. His stools and urine were repeatedly examined for ova with negative results. Cystostomy and sigmoidoscopy did not produce any evidence of schistosomiasis.

Follow-up.—The patient reported well on Oct. 18 and was carefully screened by Dr. S. D. Scott Park, who reported that there was very little abnormality at the right base; the diaphragm on the right side was very slightly elevated and not quite so well curved as on the left side; respiratory movements on both sides were equal; and the lung fields were normal (fig. 1c).

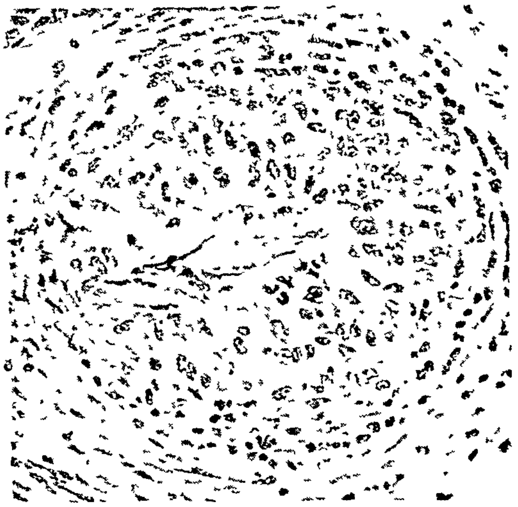

Fig. 2—A cellular "tubercle" showing in centre a schistosome ovum whose spine lies in the long axis and cannot therefore be recognised as lateral (*S. mansoni*) or terminal (*S. hæmatobium*). (× 300.)

DISCUSSION

This case is of clinical interest because the patient was unaware of his infection with schistosomes and presented no evidence of the usual bladder or rectal lesions. He had been in the habit of bathing in Lake Victoria Nyanza at Mwanza, where he was stationed in 1945, but did not realise that he ran any risk.

The ætiology of the hepatic abscess is obscure. The possible initiation of the liver lesion by *E. histolytica* and its subsequent infection by *Staph. aureus* requires consideration. Against this view is the absence of any evidence of such an infection in either gut, stool, or biopsy specimen. This fact, however, is inconclusive, for, as Dr. Robert Kirk, O.B.E. (personal communication), has pointed out, many pyogenic abscesses have been found post mortem in association with amœbiasis which had not been demonstrable in life. However, in the present case the biopsy findings were against such an explanation; moreover in amœbic abscess there is little or no leucocytosis. The patient had had a septic tooth socket, but unfortunately no bacteriological culture was made from this potential source of the hepatic infection.

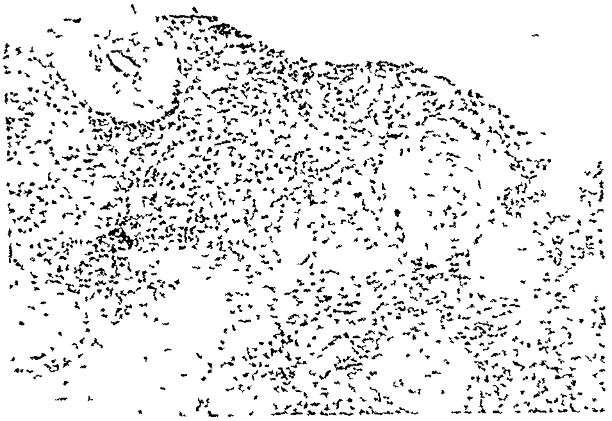

Fig. 3—Biopsy specimen from margin of liver abscess, showing two "tubercles" containing ova, one "tubercle" completely hyalinised, and one "tubercle" partially involuted. (× 40.)

Adult schistosome worms are long-lived, and it is common for active infestation to last 5–15 years; Manson-Bahr (1941) has reported activity after 20 years, and Brumpt (1936) after 28 years. It is common for the ova, especially of *S. mansoni*, instead of ulcerating through the intestine, to pass with the portal bloodstream to the liver, ultimately causing cirrhosis, without ova appearing in the stools (Byam and Archibald 1922, Brumpt 1936, Ash and Spitz 1945, Craig and Faust 1945).

This visceral form of *S. mansoni* infection is clinically difficult to diagnose and has to be considered in the differential diagnosis of every obscure abdominal case in areas where schistosomiasis is endemic. The ova of *S. mansoni* are generally found in the fæces, and those of *S. hæmatobium* in the urine, but this is not always so; the reverse occasionally happens, especially in visceral infections. The absence of ova from the urine and fæces is a point of interest in the present case.

It has been suggested that some of the obscure hepatosplenomegalies in Egypt without a corresponding lesion in the gut are caused by a toxæmia produced primarily or even exclusively by male worms. In such cases eggs in the fæces will be few or even completely lacking (Craig and Faust 1945). The occurrence of ova in our case indicates the presence of at least one female worm.

Dr. Kirk has noted that, though infection by schistosomes may cause abscesses in the intestine which are characteristic in being "eosinophil abscesses" and packed with ova, no report has been published of this condition causing liver abscess. It is generally held that the usual hepatic lesion is of the chronic type with the formation of pseudotubercles and with a tendency to fibrosis.

The suggestion that the hepatic lesion was the result of an infection with *S. mansoni* is thus the more likely one, and this probability is increased when it is recalled that infection was contracted in the more southern part of Africa. The selection of the symptomless schistosome lesion in the liver for the later pyogenic infection is of interest. Though it is possible that the schistosome infection was incidental, one is tempted to suggest that it determined the site of the later pyogenic lesion, possibly derived from the infected tooth socket.

SUMMARY

An Army officer developed a *Staph. aureus* liver abscess associated with visceral schistosomiasis.

The liver abscess was successfully treated by operation and penicillin therapy. The schistosome infection was later treated with anthiomaline.

chilblains. In 1 case capillary prothrombin-times in normal skin and from the lesion itself were estimated, but again these proved to be normal.

Clinically 23 cases responded completely to vitamin K, and 3 cases failed completely. It was not found possible to convert these failures into successes by several means tried for improving capillary circulation in the lesion itself.

No experimental evidence could therefore be adduced to support any therapeutic success of vitamin-K therapy. Neither could any support be demonstrated for the hypothesis that impaired utilisation of prothrombin in the lesions themselves might explain the failures.

I wish to thank Dr. H. Ferreira and Dr. L. W. Cann, of Ashford County Hospital, for estimating the prothrombin-times.

HEPATIC ABSCESS ASSOCIATED WITH VISCERAL SCHISTOSOMIASIS

J. GIBSON GRAHAM
M.D. Glasg., F.R.F.P.S.
ASSISTANT PHYSICIAN

J. LESLIE ORR
T.D., M.B. Glasg., F.R.F.P.S.
ASSISTANT SURGEON

WESTERN INFIRMARY, GLASGOW

LIVER abscess is rare in schistosomiasis, and in the present case the liver alone was infested and the patient had none of the usual symptoms referable to the bladder and the rectum.

CASE-RECORD

An Army officer, aged 28, had served in Madagascar in 1943 and in East Africa in 1943–45. He gave no history of any tropical disease apart from malaria. His first attack of malaria occurred in August, 1945, and he had a relapse in February, 1946, after demobilisation in this country. On each occasion he was treated with standard Army courses of quinine dihydrochloride followed by mepacrine. He considered that he had been subject to "colds" since his relapse in February. His pre-war history was uneventful save for appendicectomy in 1938, and there was nothing relevant in his family history.

On Aug. 12, 1946, the patient had a rigor followed by fever. Assuming that it was a relapse of malaria he took 2·1 g. of mepacrine over the ensuing 72 hours without any betterment in his condition, the fever (100–102°F) continuing without remission. On Aug. 15 he began to take sulphapyridine 1·0 g. every fourth hour and continued this for 24 hours, after which he discontinued it because of abdominal pain, which he ascribed to the drug, and he complained of pain in the region of the lower lobe of the right lung.

At this point the patient was seen by Dr. J. Mill Irving, of Lenzie, who noted some dullness to percussion and a diminished respiratory murmur over this area. Penicillin therapy was begun on Aug. 17 and continued till the 21st, to a total of 700,000 units. Though the patient improved somewhat he continued to look ill and toxic, and his temperature did not settle (98·4–101°F).

He was seen by one of us (J. G. G.) on Aug. 22. Expansion was slightly diminished at the right base, and there was a small area of relative dullness in the right axillary line. The respiratory murmur was vesicular, and rhonchi were heard at both bases. A small area of pleural friction was detected anteriorly over the sixth and seventh ribs. The upper border of hepatic dullness was at the level of the fourth rib. There was tenderness to palpation over the upper third of the right rectus, but the liver was impalpable.

Stools examined at this time were negative for specific pathogens, amœbæ being specially looked for. The scanty sputum did not contain acid-fast bacilli; scanty pneumococci were present. There was a leucocytosis of 18,000 per c.mm. (neutrophils 60%, lymphocytes 30%, eosinophils 3%, basophils 1%). Malaria parasites were not seen.

On admission to the Western Infirmary on Aug. 23 the patient's physical condition was essentially unchanged. A chest radiogram (fig. 1*a*) taken on Aug. 23 showed clear lung fields, the heart shadow centrally placed and not enlarged, and no elevation of the diaphragm, the excursion of which was equal on both sides, being $1\frac{1}{2}$ in. in the supine position.

Treatment and Progress.—Amœbic hepatitis was provisionally diagnosed, and a course of parenteral emetine hydrochloride gr. 1 daily was begun. There was no response, and the patient's temperature, which on Aug. 24 had been 98·4–100°F, rose on Aug. 28 to 101–101·8°F, and his pulse-rate increased from 80 to 100 per min. A chest radiogram (fig. 1*b*) taken on Aug. 28 showed the right crus of the diaphragm to be slightly elevated, and radioscopy showed that the respiratory excursion was poor on both sides, being rather less on the right than on the left side. There was no evidence of basal congestion. On Aug. 29 one of us (J. L. O.) explored the right perinephric area with a needle but found no pus. Penicillin therapy was started, 30,000 units being given every third hour, and the patient underwent operation on the same day because it was thought that an abscess was forming in the subphrenic hepatic area.

Operation (J. L. O.).—An oblique incision was made below the twelfth rib on the right side and the perinephric area explored with negative result. The twelfth rib was then resected and the subdiaphragmatic area explored without pus being encountered. A needle was next introduced into the liver, and thick creamy pus was then encountered in the right lobe near the postero-inferior margin at a depth of about $1\frac{1}{2}$ in. Pus was evacuated, drainage instituted, and a small portion of liver substance from the wall of the abscess removed for microscopy.

Postoperative Progress.—The patient made an uninterrupted recovery. Intramuscular penicillin 500,000 units daily was continued until Sept. 7. He also received gr. 12 of emetine hydrochloride, and on Aug. 30 plasma 500 ml. intravenously. The temperature fell to 99°F within twenty-four hours of operation and thereafter settled rapidly. The drainage tube was removed on Sept. 9, and the patient got up ten days later.

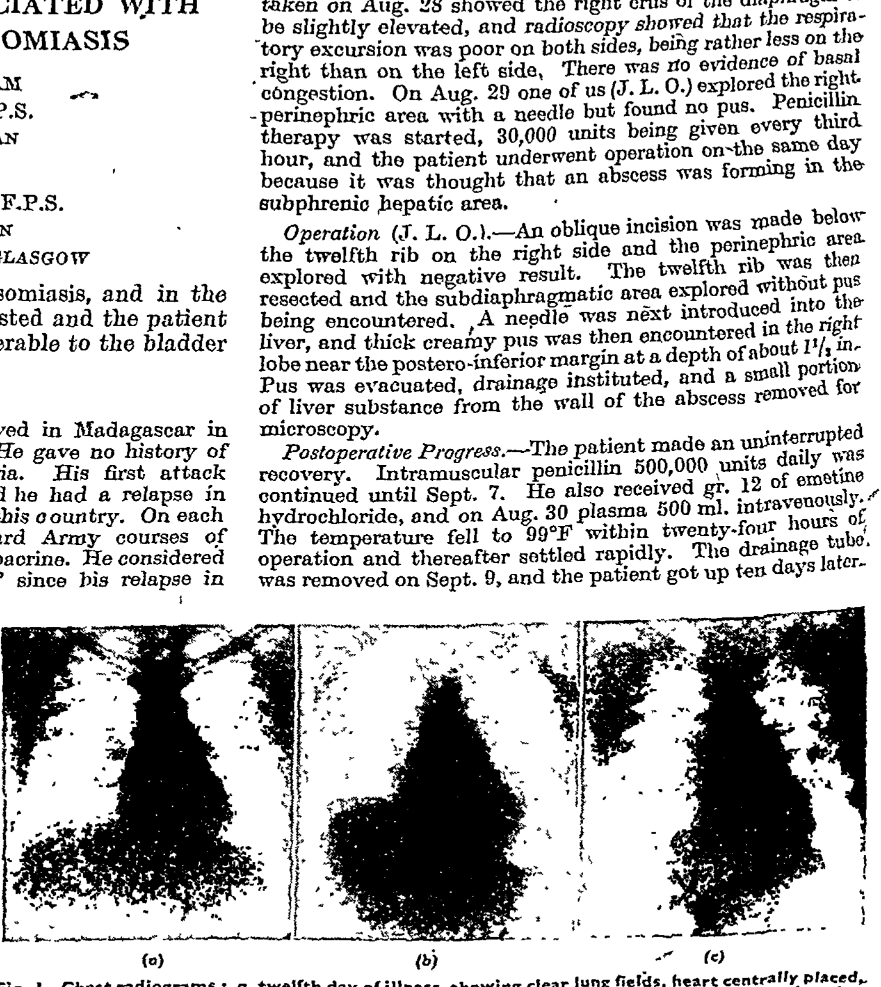

Fig. 1—Chest radiograms: *a*, twelfth day of illness, showing clear lung fields, heart centrally placed, and no elevation of right crus of diaphragm; *b*, seventeenth day of illness, showing slight elevation of right crus; *c*, seven weeks after operation, showing only slight elevation of right crus, which is not quite so well curved as the left.

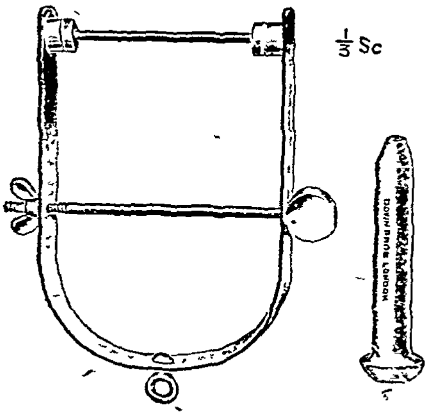
New Inventions

PIN AND STIRRUP FOR SKELETAL TRACTION

ONE of the drawbacks of skeletal traction with a pin and stirrup is the liability of the pin to loosen in the bone, sometimes to such an extent that pin traction has to be abandoned. Moreover, infection of the track in the bone commonly follows loosening of the pin. Most designers of skeletal pins have ignored this complication of skeletal traction.

Bohler, for this reason, modified his pin and stirrup to allow the stirrup to rotate freely on the long axis of the pin, thus permitting rotary movements of the stirrup without affecting the fixation of the pin in the bone. Despite the undoubted mechanical advantage of this modification, the Bohler pin is more liable to loosen in its track than the Max Page pin, which is rigidly fixed to its stirrup. Investigation of this remarkable immunity of the Max Page pin from a tendency to loosen, showed that there was another force responsible for loosening the pin in the bone—a sideways thrust of the arms of the stirrup in the long axis of the pin, a thrust which is greatly magnified by the width of the Bohler stirrup and minimised by the narrowness of the Max Page stirrup. The pin and stirrup described here (see figure) utilise both mechanical factors; the pin rotates freely within the arms of the stirrup, and the stirrup is narrow.



Another difficulty arising in the use of skeletal pins is that most pins are provided with introducing handles which jam tightly on the pin while the pin is being hammered through the bone, and the force needed to dislodge the handle often loosens the pin in the bone. To obviate this difficulty the design of the handle pin and stirrup have been altered accordingly. The pin is short and round in cross-section, with a tapering conical tip, and a tapering blunted top end. Two circular discs or flanges fit on to these conical ends of the pin. To introduce the pin, one flange is fitted on to the top end of the pin. The handle fits loosely over the top end of the pin and abuts on the flange. The mallet drives the handle on to the flange, and, when the pin has been driven home, the handle is easily removed, leaving the flange in place on the pin. The flange for the other end of the pin is now fitted on. The stirrup clips over the ends of the pin, and round sockets on the arms of the stirrup abut on the flanges. The tendency of a clip on the stirrup to spring off the pin is obviated by the strut across the arms of the stirrup, which is fixed with a butterfly nut.

The instrument is made by Down Bros. and Mayer & Phelps Ltd., of London, W.1.

Reviews of Books

The Cytology and Life-History of Bacteria

K. A. BISSET, PH.D., lecturer in bacteriology, University of Birmingham. Edinburgh: E. & S. Livingstone. 1950. Pp. 136. 18*s.* 6*d.*

WE stain bacteria in order to see them, and by staining we efface almost all that is characteristic of the living cell. The purpose of this book is to tear off the shroud and reveal the intricate structure that lies beneath. The methods are still crude; Feulgen's reaction lays bare the bacterial nucleus, and if we cannot see the genes at least we are assured that a rod-shaped organ is the bacterial chromosome. Gene recombination is deduced from the appearance of nutritionally unexacting wild-type strains in mixed populations of nutritionally exacting mutants. Sexual fusion is part of the nuclear cycle in many types of bacteria, and the mechanism differs little from that in protozoa or fungi. Bacteria are single cells, but they get round this obstacle by allocating special tasks to groups of cells, the sessile and the motile organisms, or the swarmers in *Proteus.* With numerous diagrams and photographs this book shows that while some bacteria have bad habits all of them behave much like other living creatures.

Physiology of Heat Regulation and the Science of Clothing

Editor: L. H. NEWBURGH, M.D., professor of clinical investigation, University of Michigan. Philadelphia and London: W. B. Saunders. 1949. Pp. 457. 37*s.* 6*d.*

IN the late war fighting went on in all possible climates, and detailed information was needed on the innate and external regulation of body-temperature both at rest and at work. It was especially important to know how far men could adapt themselves, and survive at extremes of temperature, so that wastage of life might be minimal and the comfort of the troops maximal. This book, written by many authors, springs from some of the intensive work, done during those years, in which civilian and Service personnel in Canada and the United States collaborated freely. Most of the work described is recent, but old and new are mingled together to give a fair picture of many aspects of temperature regulation. The first chapter tells of the adaptations of cultured and primitive man to environments varying from arctic to torrid, from wet to dry. Thereafter the book is more strictly scientific, and, before the physiology of temperature regulation and adaptation are discussed, gives some account of the factors that have to be measured and the methods used. The last section deals with the properties of materials and clothing.

The book is interesting, well produced, and thoroughly useful, collating much scattered information and covering aspects of the subject that are often ignored.

Daughters of Britain

An Account of the Work of British Women during the Second World War. VERA DOUIE, librarian of Women's Service Library. To be obtained from the author, 12, Charlbury Road, Oxford. 1949. Pp. 159. 7*s.* 6*d.*

IT would be a pity if the flamboyant title inhibited potential readers who would find this book interesting and useful. It is a sober historical account of the development of the use of women during the recent war, packed with facts and figures—many not readily accessible—which the author has wisely allowed to speak for themselves, and free from the irritating underlinings of militant feminism. Beginning with the mobilisation of women, Miss Douie deals in turn with the Services, Civil Defence, the care of the sick and wounded, transport and communications, war factories, trade unions, and food-production. The experience of earlier wars is reviewed and the story of the late war, with its slow hostile start and its rapidly accelerating development, is told with ample statistical and factual material. The book is free from sentimental anecdote, and the few stories told are amusing and graphic. The cumulative effect is enhanced by understatement. She had indeed a tale to tell.

The patient was unaware of his worm infection, and no lesion was found on sigmoidoscopy and cystoscopy. Stool examination was negative for ova or other parasites, such as cysts of *Entamœba histolytica*. The urine did not contain any eggs. The diagnosis was made by finding schistosome ova in the biopsy specimen from the wall of the hepatic abscess at operation.

The subject of visceral schistosomiasis is discussed especially in relationship to hepatic lesions likely to be caused by *S. mansoni*. The difficulty of precise identification of ova in sections is emphasised.

The liver damage caused by the visceral schistosomiasis may have paved the way for a subsequent pyogenic infection.

We wish to thank Dr. W. R. Snodgrass and Mr. George Dalziel for permission to publish this case; the members of the hospital staff for their willing coöperation; and Professor Cappell for his report on the biopsy specimen and helpful criticism.

Preliminary Communication

AMINO-ACIDS IN THE FÆCES OF BREAST-FED AND BOTTLE-FED INFANTS

VARIOUS workers have noted the wide difference in intestinal flora between breast-fed and artificially fed infants.[1] In the fæces of the breast-fed infant *Lactobacillus bifidus* predominates, whereas the artificially fed baby has a heterogeneous intestinal flora. This contrast seemed important, especially as lactobacilli are known to be very exacting in their growth requirements, particularly in respect to amino-acids. The fæcal excretion of amino-acids has therefore been investigated in two groups of healthy infants: (1) completely breast-fed; and (2) on artificial milk feeds.

METHODS AND RESULTS

The method of analysis adopted was partition chromatography, using filter paper.[2] A suspension of 2 g. of fæces was made in 10 ml. of distilled water. This was centrifuged for at least an hour, and 2 ml. of the supernatant fluid evaporated to dryness in a vacuum desiccator. The volume was made up to 0·1 ml. with distilled water, and 10–15 μl. was applied to the filter paper.

To obtain hydrolysed specimens, 1 ml. of the supernatant fluid obtained as above was mixed with an equal volume of concentrated hydrochloric acid and refluxed for 24 hours. It was then evaporated to dryness on a water bath, and again evaporated twice after the addition of 2 ml. water. The residue was made up to 0·1 ml., and 10–15 μl. was used for chromatographic analysis.

Hydrolysed and unhydrolysed specimens from 9 breast-fed infants and 11 artificially fed infants have been analysed. Two-dimensional chromatography was carried out, the solvents being butanol-acetic acid and phenol.

Breast-fed group (unhydrolysed).—Table I shows the free amino-acids present in the unhydrolysed specimens from the breast-fed infants, and the relative intensity of the spots. Alanine, glycine, glutamic acid, valine, and leucine were always present. Alanine invariably produced a spot of heavy intensity. Serine, threonine, aspartic acid, and one or more of the lysine group (lysine, ornithine, and arginine) were detected in most of the specimens. In four chromatograms the butanol-acetic acid was allowed to run off the paper, and an unknown spot just separate from valine then developed.

TABLE I—CHROMATOGRAPHIC FINDINGS IN BREAST-FED GROUP (9 INFANTS)

Amino-acid	No. of specimens in which present	Intensity		
		Heavy	Moderate	Faint
Alanine	9	9	..	..
Glycine	9	5	4	..
Glutamic acid ..	9	6	2	1
Valine	9	5	3	1
Leucine	9	2	6	1
Lysine group ..	8	..	4	4
Serine	7	1	3	3
Threonine ..	7	1	6	
Aspartic acid ..	7	..	3	4
Unknown	4	3	..	1

Artificially fed group (unhydrolysed).—Table II gives the findings in unhydrolysed specimens of fæces from 11 artificially fed infants, mostly on National Dried Milk formulæ. Compared with the breast-fed group, few free amino-acids were found, and there was no constant chromatographic pattern. Valine, of variable intensity, was the only amino-acid present in all 11 chromatograms.

Hydrolysed specimens.—The chromatographic patterns of the hydrolysed specimens from the breast-fed and bottle-fed infants were identical. They were similar to the pattern found in unhydrolysed specimens from breast-fed infants, with the addition of proline, tyrosine, and a spot in the position occupied by histidine.

With Collidine as Solvent

Using collidine in place of butanol-acetic acid as the second solvent, unhydrolysed specimens only from a further 12 breast-fed infants and 8 artificially fed infants have been analysed chromatographically. Again, the breast-fed showed an abundant and constant excretion of free amino-acids compared with the artificially fed.

TABLE II—CHROMATOGRAPHIC FINDINGS IN ARTIFICIALLY FED GROUP (11 INFANTS)

Amino-acid	No. of specimens in which present	Intensity		
		Heavy	Moderate	Faint
Valine	11	5	4	2
Glutamic acid ..	8	5	1	2
Leucine	6	1	2	3
Alanine	5	2	1	2
Glycine	5	..	3	2
Lysine group ..	2	..	..	2
Aspartic acid ..	1	..	..	1

DISCUSSION

Further investigation is required before the importance of these results can be assessed. The fæcal amino-acid excretion may obviously be related to the intestinal flora, but it is possible that the excretion of few free amino-acids (as in the artificially fed infants) may imply a state of "subnutrition" with increased susceptibility to infection. This is an interesting speculation which will require further study.

This inquiry is being made under a grant from the Scientific Advisory Committee.

THE LANCET

LONDON: SATURDAY, APRIL 15, 1950

Penicillin for Gonorrhœa

The tests of time and experience seldom justify the enthusiasm which new remedies so often arouse. Penicillin provides an exception to the rule: for few would have ventured to predict that it would be as widely useful as it has proved. In the treatment of gonorrhœa, for example, it rapidly abolishes the obvious symptoms and signs: the complications, once frequent and intractable, are now relatively uncommon; and there is no evidence that strains of gonococci have become penicillin-resistant. These results have been achieved with dosage which seems absurdly small, and there are no dangers except for the occasional possibility that the signs of early syphilis acquired at the same time may be masked or delayed. Perhaps, indeed, the real trouble about this method of treatment is that it has been too effective, and has therefore filled patient and doctor with a confidence which no remedy has ever justified. With patients it could hardly be otherwise: they are concerned with symptoms and signs, and these are promptly suppressed: the doctors who treat them have no doubts about the outcome: and, after all, penicillin has been hailed in the popular press as "the wonder drug." Of the series of 1788 male patients treated by King, Curtis, and Nicol, who describe their results in our present issue, only 403 stayed to complete three months' observation after treatment, and no fewer than 341 did not attend again after treatment had been given. The women were more faithful, yet only 265 out of 481 completed observation and 49 did not attend again after treatment. But the doctors who give treatment bear a much more serious responsibility, and it may well be that this responsibility is often taken too lightly.

Whatever may have been the case some years ago, the treatment of gonorrhœa is not now limited to specialists: many general practitioners treat such patients and some receive treatment in other special departments. Nothing has happened in the past three years which need modify our view[1] that this may be advantageous to the patients concerned, provided those who treat maintain certain standards and accept certain obligations. But there are disquieting reports that the standards then recommended are not generally observed. Far too many patients with discharges receive large doses of penicillin without any attempt at bacteriological diagnosis: and if the symptoms subside, as they often do, no attempt is made to establish cure by observation and tests. King and his colleagues contend that some of the cures claimed are apparent rather than real, and though the evidence with which they support their contention is not absolute it is highly suggestive. If the remedy is as fully effective as is generally supposed, it is certainly odd that the incidence of the disease has fallen so little in communities where the infected almost all seek treatment. In the United States it is reported that, though the incidence of early syphilis has shown a satisfactory fall, the incidence of gonorrhœa has actually risen in recent years. In this country it is true that the figures for patients attending the public clinics with acute gonorrhœa have shown some decline, but this decline is much less satisfactory than that of early syphilis. The following figures taken from the annual reports of the chief medical officer of the Ministry of Health give a basis for comparison of the incidence of gonorrhœa after the first world war and after the late war. In 1920, the year of highest incidence after the first war, the figure was 40,284; in 1921 it was 32,433, and in 1922 it was 29,477. The peak year after the late war was 1946, when the figure was 47,343; in 1947 the reported incidence was 36,666, and in 1948 it was 30,312. It does not seem likely that this decline owes much to a fully effective remedy, especially when due allowance is made for the fact that so many cases are treated elsewhere than at the public clinics and are therefore not included in the figures of incidence. If these doubts are well founded, it seems that much latent infection is being set free among the population: and we know that such infection carries a serious late legacy of incapacitating illness, both mental and physical.

Clearly the time has come for reassessment, and the plea for care and conservatism should not be ignored. Formerly gonorrhœa suffered from neglect, through indifference or despair: and it would be unfortunate if equal harm were now done through over-confidence.

---

Eosinophils and Surgical Shock

The use of adrenal cortical hormones in surgical or traumatic shock is based on Selye's concept of the "stress reaction." Under the influence of stress the pituitary gland releases adrenocorticotropic hormone (A.C.T.H.), which in turn stimulates the adrenal cortex to release its steroid hormones, particularly the so-called 11–17 oxysteroids. Adrenalectomised animals and patients with Addison's disease are specially liable to develop shock, even fatal shock, after relatively minor operations; but, by giving them large quantities of the appropriate adrenal hormones beforehand, the shock can be prevented. Furthermore, in patients with properly functioning adrenals there is a considerable increase of ketosteroid excretion in the urine after surgical operations. If, therefore, we could find a way of assessing the function of the adrenal cortex before such operations, we might detect the patients likely to have a troublesome postoperative course, and we could also tell how much of the postoperative shock is really due to adrenocortical deficiency. With this end in view, Roche and his colleagues[1] have been studying the eosinopenia that characteristically follows the administration of A.C.T.H. if adrenal function is normal.

The connection of lack of eosinophils in the blood with severe illness was noted as long ago as 1907 by Lams,[2] who also observed that the eosinophil level returns to normal or above when convalescence

[2] Lams, H. *C.R. Soc. Biol. Paris*, 1907, 62, 459.

For a book covering so wide a field and so full of matter, the general level of accuracy is remarkable. There are small errors in titles and names of bodies, and the author exaggerates the extent to which women manned searchlights in the United Kingdom; there was only one mixed regiment, and over the rest of the country the detachments were all-male. There is also a statement, generally true, that women doctors were not employed in forward units; but one (an anæsthetist) was employed as far forward as a casualty-clearing station. Occasionally Miss Douie takes sides, usually with justice—as when she castigates the Services for the poor use they made of V.A.D.S, and criticises Government policy towards the Land Army. So many facts and figures are conveniently collected here that she ought to have let us have an index.

The book was apparently written for overseas readers and has been published in this country only by the generosity of a private person. It is much the most valuable of its kind which has yet appeared.

Phenol and its Derivatives

The Relation between their Chemical Constitution and their Effect on the Organism. W. F. VON OETTINGEN, U.S. Public Health Service. National Institutes of Health Bulletin No. 190. 1949. Pp. 408. 70 cents.

THIS bulletin, like other scientific symposia published by the U.S. Public Health Service, provides exhaustive references to the chemistry and physiological action of the phenols and phenol derivatives. Their chemical manufacture, their estimation, their effect on the skin and other organs, their antiseptic action, their toxicity, their excretion, and the possible treatment of toxic effects are all analysed. The mechanism of the physiological action is described and where possible the effect of the compound on various enzymes and enzyme systems is discussed. In the case of related compounds and compounds of a homologous series the various properties and effects of the compounds are compared and contrasted. Throughout the book the information is summarised by clear tables. Among the important compounds considered, in addition to the more usual phenols, are the halogenated phenols and the mono- and di-nitrophenols; adrenaline and its derivatives are not mentioned. The importance of most of these compounds in modern chemical industry and the possible hazards arising from their use makes the information valuable to those who are interested in industrial and occupational diseases.

Das Menschliche Knochenmark

(2nd ed.) KARL ROHR, University of Zürich. Stuttgart: Thieme. 1949. Pp. 404. D.M. 47.50.

THE first edition of this book appeared in 1940 and so is more or less unknown here. The second edition is a typical up-to-date Continental textbook, drawing little on American, and still less on British sources. Rohr treats bone-marrow as an active tissue with supporting structure, blood-supply, and nerve-supply, engaged in the production of blood cells of many kinds. He deals with its development, its anatomy, its physiology, its general pathology, and the pathology of its separate parts, giving most space naturally to the pathology of development of the various blood cells, but also taking in conditions that affect cell-development secondarily, like myelosclerosis and secondary tumour infiltration. This is a large programme, and it is extended at many points by excursions into general, but not exclusively clinical, hæmatology; for instance, several pages are devoted to a discussion on the nature of leukæmia—that is, to Continental views on this question.

The programme is thoroughly, even exhaustively, carried through, and there are many interesting parts. The embryology of bone-marrow is very well described, and Rohr adheres to the view that the first erythroblasts are megaloblasts; fig. 45 shows in schematic form an original view of the relation of embryonal and adult blood-cell production. Some parts of hæmatology regularly get more notice in Continental than in English books; so in Rohr's book we find a discussion of the place of the tissue "mast" cells illustrated by a colour plate; the reticulum cell with its relations the histiocyte and the monocyte is thoroughly dealt with and copiously illustrated. Rohr accepts the existence of intermediate forms between megaloblast and normoblast. He describes and illustrates an unusual form of human erythroleukosis.

All hæmatological books should be well illustrated. The illustrations in this one are designed to fit the text and are not for reference on their own. Most of them are monochrome photographs of marrow smears and sections. There are 24 colour figures reproduced moderately well at a reasonable size from paintings. Finally, there are 35 pages of references, but there are many omissions of American and English work published between 1939 and 1946.

Fifteen years ago it was still essential to read the German texts if one was really to know something about hæmatology; but in 1950, it is no longer necessary. Though Rohr's book is a comprehensive account of the subject, most readers will get all they want from English texts.

Masochism in Modern Man

THEODOR REIK. Translated by MARGARET H. BEIGEL and GERTRUD M. KURTH. New York: Farrar, Straus & Co. London: Allen & Unwin. 1949. Pp. 439. 25s.

MASOCHISM has been the centre of an important controversy among psycho-analysts. Dr. Reik, who as one of Freud's early pupils and friends worships him this side idolatry, takes up critically some of the master's theories about the nature of the strange link between pain and pleasure which masochists seem to exhibit. He holds that this link is not an intrinsic one, that the pleasure follows the pain, instead of coinciding with it, and that suspense and demonstration are specific characteristics of masochism in all its forms. He thus builds a bridge between masochism, the sexual perversion, and the many forms of gladly accepted suffering which have no manifest sexual component. After stating the problem, he examines the phenomena, and singles out the masochist's fantasy, his tension through suspense, and his effort to display his humiliation and suffering to others. The dynamics and origin of masochism, its relation to femininity, the gains it brings to the ego, its social forms, especially in religion, and its cultural aspects are reviewed in turn. The book contains much stimulating material, and is written in lively straightforward language.

Mobilization of the Human Body. *Newer Concepts in Body Mechanics* (Stanford, Calif.: Stanford University Press. London: Oxford University Press. 1949. Pp. 65. 16s.).—This book presents in a concise form the methods of physical reablement used by Dr. Harvey E. Billig, jun., and Miss Evelyn Loewendahl, the authors, at the Billig Clinic, Los Angeles. They emphasise the effects of poor posture on the ligaments and fasciæ of the body, and give passive stretching technique, both for testing the shortening of such structures and for restoring mobility. This particular emphasis is refreshing in contrast to the usual pure muscle re-education: but it is not in fact as new as the authors would have us believe; cervical, dorsal, and hamstring stretchings, for instance, are widely used in clinics here. The photographic illustrations show rather clumsy grips on the part of the physiotherapist, who often kneels on the patient's couch. Coordination, rhythmic exercises, and the basic neuromuscular mechanism are briefly touched on.

Handbook of Digestive Disease (2nd ed. London: Henry Kimpton. 1949. Pp. 658. 75s.).—This handbook of digestive diseases is an expansion of Dr. John L. Kantor's original "Synopsis," and now covers over 600 pages, with nearly 150 diagrams and illustrations. With the help of Dr. Anthony M. Kasich, Dr. Kantor presents the subject fully and clearly, and the work is sufficiently documented to be useful even to specialists in gastro-enterology. But its main appeal will be to general physicians and practitioners, who will find in it a concise and comprehensive account of all the important digestive disorders, with some excellent illustrations. The style is pleasant and easy—not specially impressive, but informative and eminently readable. Divergent views on ætiology, treatment, or pathology are fairly given and the reader is left with no more than a gentle bias towards one outlook or another. The background of physiology is good. The book includes four chapters on diseases of the liver and gall-bladder, and an interesting though brief chapter on the psychiatric aspects of digestive disease. There are remarkably few omissions.

Northern Rhodesia, in which an African boy, infected by a virulent strain of *S. typhi* rich in Vi antigen, seemed to be recovering well with chloramphenicol but collapsed suddenly and died in the second week of the disease. But the consensus of opinion is in agreement with Dr. EDGE, who reviews his 16 cases on p. 710 and remarks that the "complete transformation in a few days" can only be fully appreciated by clinicians who recall their own helplessness in the past. In our columns a fortnight ago, GOOD and MACKENZIE,[9] and RANKIN and GRIMBLE [10] recounted their experiences with chloromycetin in typhoid patients, mostly from the small outbreak in Crowthorne, Berks, in April–May, 1949, which affected about 40 people. A trial under controlled conditions was arranged, using a strict "alternate case" method of selection. GOOD and MACKENZIE thus had a group of 6 cases receiving chloramphenicol and a control group of 7 cases, though 3 of the controls were later treated with chloramphenicol when they relapsed. The results were not so satisfactory as might have been expected from the first impressions gained during the trial, published in a preliminary note by BRADLEY.[11] There were 3 relapses in the original treated group and 3 in the controls, and the only persistent excreter identified in this outbreak was one of the female patients in the treated group. Nevertheless, GOOD and MACKENZIE, like all previous observers, reach the conclusion that chloramphenicol is the most valuable drug we have against typhoid fever. The 18 cases reported by RANKIN and GRIMBLE comprised 10 patients from the Crowthorne outbreak, which was caused by a strain of Vi-phage type E1, and 8 sporadic cases treated in the subsequent six months and due to strains of unspecified, and presumably different, Vi-phage types. The virulence of typhoid strains isolated in different outbreaks, and the severity of the disease they cause, vary so widely that one cannot regard these sporadic cases, which received no chloramphenicol, as satisfactory "controls." A similar criticism applies to the report by EL RAMLI [12] from Cairo in the same issue. His series consisted of 200 cases of typhoid fever treated with chloramphenicol at the Abbassia Fever Hospital between May and December, 1949. The average duration of fever after the start of treatment was 3·5 days and the relapse-rate was 27·5%. EL RAMLI did not feel justified in leaving some of the patients without chloramphenicol as controls, so he compared the case-mortality of 6·5% in his treated series with that of all the typhoid cases treated at the same hospital over the past ten years (9–12%). It must be borne in mind here in the small typhoid outbreaks that occurred among British troops in Egypt during the past few years the fatality-rates, in patients receiving no specific treatment, ranged from nil to well over 25%. EL RAMLI also observed in 7 very severe cases that the temperature did not settle quickly but remained high for eight to twenty-seven days. His general conclusion is that chloramphenicol provides the most efficient specific treatment for typhoid fever so far devised, but he hopes to improve the results by combining chloramphenicol with sulphadiazine treatment, as was suggested by EL BOROLOSSY and BUTTLE.[13] In view of the extreme degree of toxæmia commonly seen in severe typhoid cases, however, a combination of chloramphenicol and a potent "Vi + O" anti-typhoid serum, such as that recommended by FELIX,[14] might prove more effective.

One aspect of the typhoid problem has received very little attention in the reports on the use of chloramphenicol in the acute disease. Will the new antibiotic prevent the development of the chronic carrier state and thus contribute towards the ultimate goal of eradicating typhoid infection? This question is of paramount importance and deserves the urgent attention of both public-health officers and laboratory workers. GOOD and MACKENZIE obtained some valuable data by observing the effect of chloramphenicol on the excretion of typhoid bacilli both during and after treatment. The findings in their small series were disappointing and recall the observations made on typhoid cases treated with penicillin and sulphathiazole combined.[15] It may be concluded that the dosage adopted by GOOD and MACKENZIE, which was that originally suggested by WOODWARD and his colleagues, cannot prevent either clinical relapse or the development of the chronic carrier state. Lately SMADEL and his colleagues [16] have advised that treatment should be continued for about fourteen days with a total dosage of about 25 g. But they do not say what effect the larger doses given over longer periods have on the excretion of typhoid bacilli in the fæces and urine. That longer treatment is no guarantee against relapse is seen from the experience of RANKIN and GRIMBLE,[10] who describe a typical relapse in a patient who had received 37·5 g. of chloromycetin in twenty days. The latest suggestion by WOODWARD (quoted by SMADEL [17]), that intermittent short courses of chloramphenicol should be given, was followed in the outbreak at Salford in October, 1949, but the effect on the excretion of typhoid bacilli was no better than that of the original regimen.[18]

The closest coöperation between clinician and pathologist is clearly essential in the planning of future therapeutic trials. This coöperation has not been conspicuous in some of those so far carried out here or abroad. The effect of the drug on the bacteræmia can be assessed only if the organism is shown to be present in the blood-stream immediately before the drug is exhibited and its presence or absence is checked in blood-cultures taken at regular short intervals afterwards. The effect of the drug on the excretion of the organism can be assessed only if bacteriological examinations of the fæces and urine are begun early in the disease and continued at regular and short intervals until convalescence. These simple rules have not always been observed. When it is intended to conduct a trial under controlled conditions, using "alternate case" selection, and the patients come from small groups infected in different localities in an endemic area, equal numbers of cases infected from the same source must be allotted to

sets in; eosinophilia, in his view, is a good prognostic sign. Roche and his colleagues have used the modern wet count of eosinophils, which is much quicker and more accurate than indirect estimation from a differential count on a stained film. They confirmed that a surgical operation is soon followed by a profound fall, and often a complete disappearance, of eosinophils in the blood. This eosinopenia is most severe 5–8 hours after the operation begins, and it persists for some hours; but usually by 24 hours recovery has begun and the eosinophils rise again, often reaching levels above the normal in the next 7 days. Now, as a rule the level of eosinophils in the blood at any one time means little; it is the change in that level under different conditions that matters. But it is clear that if in the period from 4 to 24 hours after the start of a surgical operation the patient's eosinophil level is very low, it can be assumed that the adrenal cortex is functioning properly, and even if the patient is shocked there is no indication for giving adrenal cortex hormone. The only cautions are that the patient must not have an aplastic bone-marrow, or an allergic eosinophilia. To illustrate their point, Roche and his colleagues quote a very striking case. In 12 normally reacting patients, the eosinophil levels in the blood 10 hours after operation were about 0–5 per c.mm. The unusual patient was a man operated on for a suspected lesion of the sigmoid colon who was profoundly shocked afterwards; his blood eosinophils 10 hours postoperatively were 260 per c.mm.; the patient died in spite of the administration of adrenal cortex hormones, and at the necropsy he was found to have tuberculosis of both adrenal glands, only a little functioning gland remaining.

It is evidently important that we should know the state of the patient's adrenocortical reserves before operation, so Roche and his co-workers have devised two tests to provide this information. The first uses A.C.T.H.: after blood for the eosinophil-count has been taken, 25 mg. of A.C.T.H. is injected intramuscularly and 4 hours later the eosinophil-count is repeated; the fall must be at least 50% to indicate that adrenocortical reserves are normal. The second test is based on the observation that a small dose—0·3 mg.—of adrenaline will also cause a fall in circulating eosinophils; it is thought that the adrenaline acts on the hypothalamus or the pituitary which in turn stimulates the adrenal cortex. The test is thus one of pituitary-adrenocortical reserves. It is carried out by injecting 0·3 mg. of adrenaline subcutaneously and counting the blood eosinophils 4 hours later; again a fall of 50% or more indicates normal reserves.

These tests were tried on two patients with pituitary lesions who might well have had a stormy postoperative course. The first patient had had intensive X-ray therapy of the pituitary gland for Cushing's syndrome 10 months before she was admitted to hospital for a hysterectomy. With both adrenaline and A.C.T.H. tests there was a significant fall in eosinophils, which suggested that the operation could be undertaken without undue risk. The operation was duly performed, and recovery was uneventful. The second patient had a chromophobe adenoma causing visual impairment; with the adrenaline test the eosinophils actually rose slightly, while with the A.C.T.H. test only a 15% fall was recorded. Difficulties were anticipated and an attempt to begin the operation failed because of shock caused by the anæsthetic. She was therefore treated for 6 days with large doses of A.C.T.H., by which time the eosinophils in the blood had fallen 75% and the urinary excretion of ketosteroids had increased from 0·9 to 8·9 mg. in 24 hours. The operation was then performed without incident, and, though the patient had a difficult time after the operation, she recovered satisfactorily. The number of cases reported by Roche et al. is small, but their work is sure to be repeated, and if it is confirmed the surgeon will want to know his patients' eosinophil-counts. Stimulated by the work with A.C.T.H. in rheumatoid arthritis, the technique of eosinophil counting is being improved. Most laboratories use Dungar's method in some form, but this has disadvantages, especially for large-scale use; methods like that of Randolph,[3] which use propylene glycol in the diluting fluid, are coming into use.

Apart from its immediate importance, there are two interesting points about this work. It is one of the first applications of A.C.T.H. and its effects as a "research tool" in conditions other than rheumatoid arthritis. And the results suggest that shock due to failure of adrenal cortical function is likely to be distinctly rare, so that large amounts of adrenal cortical hormone will be saved for the patients who really need it.

Chloromycetin in Typhoid Fever

Until lately typhoid fever had resisted all attempts at chemotherapy. Most of the sulphonamides introduced in the past fifteen years have been tried in this disease, but the initially favourable claims for several of them were soon disproved. The same process has been repeated with each of the antibiotics hitherto tried—penicillin, streptomycin, aerosporin (polymyxin), and 'Aureomycin'—and even the promising results reported with penicillin and sulphonamides combined have not been repeated. There is good reason, therefore, for caution in interpreting the remarkable clinical effects of chloramphenicol.

In the last few months an increasing stream of clinical reports have appeared in this country and abroad confirming the original observations of Woodward and his colleagues [4] with chloromycetin in the treatment of typhoid patients in Malaya. Some of these have already been reviewed in these columns.[5] The drug's action on the constitutional symptoms are so striking that the clinicians are unanimous in acclaiming its value, even though some failures have also been recorded. Thus, out of 6 severely ill patients treated in Bombay by Patel et al.,[6] 3 died and 1 relapsed; and in a series of 63 patients treated in Italy by Conti and his colleagues [7] there were 4 deaths and 9 relapses. Dana et al.[8] have described 5 cases treated in Tunis which showed an alarming rise in blood-urea; 3 of these patients died, but the other 2 improved when the chloramphenicol was stopped and they eventually survived. In our correspondence columns this week Dr. Stephens reports a case from antigens. On the other hand, for protecting mice against *Bact. coli* infection, serum from a calf immunised with endotoxin proved about 30 times more potent than a commercial *Bact. coli* antiserum. Possibly, therefore, a serum could be prepared that would protect young calves against "white diarrhœa," and the immunity might extend to other members of the colon-typhoid group. If it is true that most of the lethal effects of infantile gastro-enteritis are caused by special strains of the colon-typhoid group, as suggested by the work of Giles and Sangster[2] and Mackerras and Mackerras,[3] a similar serum might be valuable in this condition. If really potent, it should at least help in elucidating the ætiology of the disease.

THE AGED WHO ARE MENTALLY INFIRM

MANY old people suffering from relatively mild degrees of mental infirmity have of recent years been admitted to mental hospitals under certificate, largely because there was nowhere else to send them when they were sick. This desperate resort has blocked mental-hospital beds which could be used for the treatment of acute and recoverable patients of all ages. The Ministry of Health[4] has therefore asked the regional hospital boards to consider providing, for people of 65 and over who have deteriorated mentally, both short-stay psychiatric units and long-stay annexes.

In the future, geriatric departments are to be developed in the larger hospital centres, usually in the general hospital of a group; and the Ministry propose that each such department should include a short-stay psychiatric unit capable of dealing with elderly patients whose mental state does not call for immediate mental-hospital treatment. Such a unit will be used to establish the diagnosis and give short-term treatment; and the stay of any patient will not usually exceed 6 weeks. Some of the patients will be well enough to return home after treatment, some will need care in long-stay annexes, a few will need mental-hospital care, and a proportion will die. It is suggested that the wards should not hold more than 25 beds, and should be divided up so that patients can be classified into small groups; a few single rooms should be available.

Long-stay annexes are to be provided for patients without serious behaviour disorders, as distinct from the more disturbed types. The Ministry thinks it may be convenient to associate such annexes either with mental hospitals, general hospitals, or hospitals for the chronic sick, depending on local conditions. At all events they should be within convenient reach of most visiting relatives or friends. If they are in buildings actually in the mental-hospital grounds they should cease to be a part of the hospital and should have a separate entrance, but they should none the less be linked with the mental hospital in some way, since the staff should include mental nurses and psychiatric social workers, and the medical care should be supervised by a psychiatric consultant.

The object is not to set up new mental hospitals for the treatment of acute psychoses; and the Minister is therefore willing to direct that long-stay annexes shall be used "for the reception of persons who are suffering from mental infirmity due to old age and who do not require detention." This gets rid of any question of certification. Mental deterioration associated with grossly disturbed behaviour will, as formerly, be treated in a mental hospital, and so will acute recoverable mental illness. Patients will be referred to the long-stay annexes from the short-stay units, or sent direct from their own homes by the family doctor attending them. The Minister specially recommends that the long-stay annexes should be "simple and home-like in character."

USE OF PETHIDINE BY MIDWIVES

THE Dangerous Drugs Regulations which came into force at the beginning of this month authorise the possession and use of pethidine by midwives. The value of pethidine in obstetrics is now well established, and the new regulation is welcome. It marks a further step in the growing recognition by the medical profession and the Home Office of the wisdom of allowing preparations classed as dangerous drugs to be supplied to trained persons who are not medically qualified, for relief of pain under special circumstances. The careful framing of the regulation leaves little possibility of abuse; the safeguards might even be termed drastic. The amount to be supplied is limited to the quantity of pethidine which would be necessary for the administration of 200 mg. to each pregnant woman whose name is recorded in the personal register which it is already obligatory for the midwife to maintain. A record of supply and administration of the drug must be kept; and, of course, when not actually in use, the pethidine will be kept under lock and key. It is presumed that full instruction in the use and limitations of pethidine will be a part of the course of training of midwives, and that it will be emphasised that the drug is intended for use only when the patient is in labour. It should not be necessary to remind the midwife that if the patient has to be referred to a doctor or transferred to hospital, full information about the use of analgesics should be given.

This new regulation should go some way towards solving the difficult problem of how best to equip the midwife to supply analgesia to women who are being delivered at home. Pethidine has now[1 2] been shown to be a safe analgesic, easy to give and with few side-effects. Used with discrimination, it should be of considerable value, and we hope that after a year or two an attempt will be made to assess the results. In conclusion, dare we hope that further regulations will be made to allow of the wider use of analgesics in first-aid?

TEACHERS ON TOUR

MANY people have said that it is important that the periphery of medical practice should be more closely linked with the centre. Practical schemes to further this agreed policy are less common. But last month Manchester Regional Hospital Board approved two interesting suggestions to this end put forward by Sir Harry Platt. During the past two years some half-dozen orthopædic conferences have been held at strategic points in the region, and the success of these meetings led Platt to suggest that the time had come when the system should be extended to other subjects. A beginning might well be made, he thought, with conferences on general medicine, general surgery, obstetrics and gynæcology, and pædiatrics.

His second suggestion breaks fresh ground. He proposes that not less than once a year a visitor distinguished in one of the main clinical fields should be invited to spend a week, or better still a fortnight, at each peripheral key centre. There he would take charge at the local hospital of the clinical department of his own specialty, conduct ward rounds, and give talks. On one or two evenings there might be discussions to which the general practitioners of the area would be invited. Judging by the enthusiasm for surgical Saturday afternoons which Dr. Collings observed in the Highlands of Scotland, this might well be one of the best parts of a good idea. Platt is keen that the distinguished visitor should live in the town and get to know some of

the treated and the control groups. Single sporadic cases cannot be included in a "controlled" trial, because there would then be no control cases from the same source of infection. Vi-phage typing of the strains isolated from the treated and the control cases should be carried out as a routine. The result will confirm or disprove the epidemiological connection between alternate cases. Finally, a thorough serological and bacteriological study should be made of the convalescent patients for three to six months after their discharge from hospital, to make certain that they do not become chronic carriers.

Annotations

LORD MORAN

WHEN in 1941 the Royal College of Physicians elected Sir Charles Wilson as president, it certainly did not foresee that for eight more years his re-election would be an annual event—and an exciting one. Whatever else his critics may say of his nine years' presidency, they cannot fairly describe it as dull; nor did it end tamely. Lord Moran is not one of those who hold that because an institution is old it should reduce its activities and live gracefully in the past: he regards prestige as useful rather than ornamental. Since 1941 constructive proposals have come from the college in reports of committees on social and preventive medicine, psychological medicine, medical education, pædiatrics, neurology, pathology, dermatology, cardiology, and rheumatic heart-disease, and on problems of demobilisation. The Prophit report on tuberculosis came out in 1948, and an International Conference of Physicians was held in 1947. Internally the members have been given opportunities of meeting to express their views, and representation on the council. Externally the Physicians have joined with the Surgeons and Obstetricians in a standing joint committee; but they have preferred to remain in Pall Mall rather than form part of an Academy of Medicine in Lincoln's Inn Fields.

In the preliminaries to the National Health Service, the attitude of the Royal College of Physicians, expressed, and to some extent formed, by Lord Moran, was that the creation of a service was inevitable and that their duty was to help in fashioning it, so that avoidable mistakes might be avoided. Probably it would be correct to say that if the senior college had taken a different line, the profession would have refused to work the service, unless or until compelled to do so. On the narrower issue of the future of consultant practice, Lord Moran believed that grave harm would be done to the whole profession if the highest incomes open to doctors in the service were to be no more than the £2500 a year paid to medical professors; and his arguments in the House of Lords led to the formation of the Spens Committee on the remuneration of consultants, of which he was a member. This committee's report, and its acceptance by the Government, has created confusion wherever medical men are publicly employed; but in the end the whole quality of public service is likely to gain by the committee's stand against the old tradition that public servants must be poorly paid. The committee's further proposal that the highest salaries should be awarded only for special merit, as judged by a man's peers, has led to what we regard as a most important experiment in the technique of public service under the new conditions. For the fact that this experiment is being made, and that the profession has not accepted a conventional system of remuneration on Civil Service lines, we have to thank both Lord Moran and the Minister, both men of imagination.

Lord Moran's qualities are admired most, perhaps, by those who know him best; but even those who deny the wisdom of his policies must be impressed by the courage with which he has pursued them. To his successor, Dr. Russell Brain, he leaves a difficult task, but one whose responsibility he has enhanced.

NEW LIGHT ON ENDOTOXINS

IT has been recognised for some time that the toxic properties of the colon-typhoid-dysentery group, with the probable exception of *Shigella shigæ*, are attributable to a nitrogen-containing polysaccharide complex. Some authors call this substance a somatic antigen and others an endotoxin. It has been extracted from bacterial bodies with trichloracetic acid (Boivin and Mesrobeanu 1933), by tryptic digestion (Raistrick and Topley 1934), and with diethylene glycol (Morgan 1937). It is antigenic; it produces a pathological picture in which the fundamental change is a terminal circulatory hypertension; it causes hyperthermia, transient hyperglycæmia (followed by hypoglycæmia), placental hæmorrhage with abortion, and hæmorrhage in implanted tumours; and its toxicity appears to be less in animals injected with adrenal cortical extract.

When endeavouring to explain the toxicity to guineapigs of some heat-killed saline suspensions of *Bacterium coli*, Roberts[1] found that the toxic substance was a polysaccharide complex, or endotoxin, and that it was present in filtrates of heated suspensions. The high susceptibility of guineapigs (but not mice) and the presence of endotoxin in the filtrate of heated saline suspensions, seemed to conflict with accepted knowledge, and further investigation was therefore undertaken. *Bact. coli* was grown in a synthetic medium vigorously agitated by aeration, and viable counts of 25,000 million cells per ml. were obtained. When these suspensions of *Bact. coli* were heated at 80°C for one hour, almost all the endotoxin entered the suspending fluid and could be recovered from the filtrate. On purification it proved to have the physical, chemical, and biological properties associated with the endotoxins of salmonella and dysentery organisms.

These observations were made by employing guineapigs to detect the endotoxin. Experiments on purified endotoxic complex showed that even when guineapigs were injected subcutaneously and mice intravenously, the guineapigs were, weight for weight, 17·5 times more susceptible than mice. It is possible that guineapigs may be more susceptible to *Bact. coli* endotoxin, and more uniform in their response to it, than to the endotoxins of other enteric bacteria. The gross appearance of lesions in guineapigs suggested capillary hæmorrhage, but microscopical examination did not indicate whether the lesion was due to extravasation or to hypertension. When the trypan-blue technique of Menkin (1938) was applied, no evidence of increased capillary permeability could be obtained. The results thus supported the view that the lesion was a terminal hypertension.

These simplified methods of producing large quantities of *Bact. coli* in synthetic medium and of obtaining the endotoxin will no doubt stimulate further studies in this field. It also looks as though much work on antigenic analysis may need re-examination, because the bacterial suspensions have often been killed by heat, which evidently removes the antigen from the bacterial bodies. Though an active immunity was demonstrated in surviving guineapigs, there appears to be no immediate likelihood of developing a method of detoxifying endotoxin for purposes of immunisation; and, as bacterial cells are as effective as the complex in stimulating immunity, there is no obvious advantage in using endotoxin instead of bacterial suspensions as

Points of View

THE HEART OF THE MATTER
or
General Practice, The Act, and The Devil

Being extracts from the first Bevan lecture delivered at the Academy of Medicine, Lincoln's Inn Fields, by

A G.-P. SURGEON

> 'All the Breath and Bloom of the year in
> the bag of one B'!
>
> BROWNING

MY LORDS PRESIDENTS OF THE ROYAL COLLEGES OF PHYSICIANS, SURGEONS, AND OBSTETRICIANS,—It is indeed a privilege you have given me by honouring me with the first Bevan lectureship. It is as yet early days to condone or condemn the National Health Service Act, which would have been passed in some form or other whatever political party might have been in power. Today I wish to give you my views, and if at times you think they are unreasonable, or unduly harsh and critical, I would only plead that they are my interpretations, after 25 years' general practice, of what the ideal should be. After all, the experience of the man in the field should be sought, and what advice he offers should be heard and within reason acted on.

* * *

The average patient is not concerned with his rhesus factor or his blood-cells: he comes to his doctor for comfort and reassurance. But what is happening? Are we stark, staring, raving mad? We are creating a race of hypochondriacs. Our doctoring is being guided and dominated by the huge medical commercial firms and their showers of circulars. We are handing out the material things—teeth, spectacles, corsets, and medicines of every expensive variety by the ton—all at colossal expense.

Why all this attention to teeth and why start the scheme the wrong way? Free dental treatment should be concentrated on youth up to 18 years. After that until the 70s everybody should make his own arrangements. (The septic tooth causing all the body ailments was long ago a busted flush.) But can you get school dentists now? No!

I have many friends in the dental profession, and at their job they are first-class. But they look after only one orifice of the body—we do the lot, and I assure you the aft one is of equal importance to the for'ard. When a dentist is allowed to sign a death certificate; when he can diagnose an acute abdomen; when he can stay up all night with an obstructed labour; when he can comfort a mother for the loss of her only child—then, and then only, will I regard him as on an equal professional basis. Until then, he is a highly skilled mechanic at one job. Yet you pay him the sky!

The less said about the other material benefits the better—again a matter of understanding of people. Is it likely that Mrs. Smith will get away with new spectacles, corsets, and elastic stockings without Mrs. Jones wanting to have them too? Under the health scheme half a million prescriptions are issued per diem! What a race! What a people! What positive health! Don't blame the poor practitioner—you put him there with a limitless tariff and a waiting-room of 50 people. Feed them properly and house them—it is much cheaper in the long run.

* * *

Today half the practitioner's patients want some form of certificate—not medical advice. That is not doctoring. We are not here to do that kind of job: we are here to advise the sick and worried, to give them comfort, to ease their burden of the day, and when their time comes to go to lighten their last journey. We cannot go on as we are.

Yes, look after the babies and children. Look after the old; don't throw them on the dust-heap but rather get the Chinese attitude of respect and care for the aged. (I would even go further and make it compulsory for near relations to care for their elders, and then we should be able to get the remainder—the real unwanted—into our chronic hospitals.) But from adolescence to the 70s, disease as disease is rare; the individual should be capable of looking after himself, and sickness benefit should not be made so easy to get as it is today.

And the doctor must be largely dissociated from certification of sickness. You say this is impossible? It is not. Let the patient see the doctor, or the doctor visit the patient, but purely because the patient wants medical advice and not because the doctor has to cover illness from a certification point of view. What one may call "short certification"—that is, a few days to a week—is the curse and bane of the practitioner. Trust your workman, I would say to the benefit society: it would soon level out and one would soon find out.

The doctor must be independent—must—must—must be free from the fear of losing his patients unless he plays to their certification whim. Unless this is done the whole fabric of practice is undermined; and remember, the practitioner sees the patient first. Then, what a joy to the doctor, when he sees his waiting-room full of people, to know they are there to see him—for his advice—for his knowledge—for his skill! Whether their ailment is trivial matters not one iota: "I can treat them and comfort them." But if the practitioner is going to be subservient to certification of any kind—law, societies, or Government—well, we are going to Hell and going very fast. He must remain the independent individual, fearing no-one and fearing only for his patient. Yes, let the patient be absolved from the financial burden of illness, but let us practise our profession as individuals and on our sworn oath when we qualified. You cannot legislate the good practitioner—you might as well try to legislate the good poet.

* * *

The practitioner is the rock-bottom basis of medicine in a community, and is rightly guarded by the most stringent principles of conduct. But what is happening today to the training of future practitioners? The Goodenough report, admirable though it was, hardly touched on the training of the practitioner as a practitioner. Disease as a clear-cut entity is rare: the good doctor treats the patient first and the disease afterwards—it is the man that matters. It is most extraordinary that not a single medical school in the country has lectures by practitioners to tell the young, to guide them in the pitfalls, and to tell them about people and "cabbages and kings." I would humbly suggest that the medical schools could pick out a hundred practitioners who would give first-class lectures on their job. It would be no bad idea to institute university chairs of general practice—it would pay a handsome dividend in the long run and bring a human touch to a possibly over-academised teaching school. Today the tendency is to specialise, and the young man sees the potential glittering prizes and the easy way of life. More and more specialist departments are created, and one can be quite certain that whoever is in charge of such a department will see that it is justified and continued—otherwise his living goes. The churning out of specialists at the moment fills me with horror: soon there will be no doctors but all specialists.

Today X rays are to medicine what the B.B.C. and television are to the general public—an ancillary diversion—grossly over-used—abused—an escape mechanism for diagnosis, as the B.B.C. is an escape from facing life. This is a hard statement, but it is true and you all know it.

its citizens as well as its doctors, especially the people responsible for managing the hospital group. He suggests that visitors might be chosen from such people as local regional advisers, consultants, specialists from other regions, and university professors. The invitation should come from the regional board with the backing of the local management committee and the staff of the hospital where the visitor would work. To be a visitor will clearly not be an easy task, but Platt feels sure that it would be possible to find senior men ready to give the time and to take the trouble. Obviously it would be a useful job. To bring the teacher to the postgraduates rather than to draw the postgraduates back to the teaching schools may be a new idea, but it would probably ensure that the teacher reached more postgraduates. Incidentally he might himself gain a clearer idea of the problems of medicine in peripheral practice.

ADMISSION AND DISPOSAL

ONCE again the difficulties of admission to hospital have appeared in the newspapers. In the latest case a woman of 80 with a fractured femur was taken by accident ambulance to a teaching hospital, which was unable to find a bed for her; so she was given some tablets and sent home with a message to her doctor that he should endeavour to get her admitted to some other hospital. This strange procedure on the part of the teaching hospital which sent the patient home rather than search for a bed elsewhere is symptomatic of the awkward relations now prevailing between teaching and other hospitals. The teaching hospitals naturally hold that they must keep a proper balance of cases in their wards for teaching purposes. Before the health service started this was achieved by the simple process of passing on unsuitable cases to the local county hospital. But unfortunately it happens that cases not suitable for teaching are usually those that are generally unattractive to hospitals. Now that the ex-county hospitals are under no obligation to take local patients, they understandably object to taking all the uninteresting ones from the neighbouring teaching hospital. They say, with some reason, that if the teaching hospital's beds are full, so are theirs, and that if the patient is in a teaching hospital he had better stay there.

On the one hand, the new system by which long-term patients may be retained in the general wards of teaching hospitals is both bad for teaching and grossly extravagant. On the other hand, the old system by which teaching hospitals disposed of their cases cannot be restored without exciting serious ill feeling among those hospitals which would have to take them. This being so, the solution seems to be that teaching hospitals should have annexes to which they can pass on such long-term cases as they may involuntarily acquire. By this means it should be possible both to avoid friction with the non-teaching hospitals and also—since a bed in an annexe could be maintained at less cost than a bed in a general hospital—to save a considerable amount of money.

PROPHYLACTIC INOCULATION AND POLIOMYELITIS

LAST week we commented on the association found by McCloskey in Australia between prophylactic immunisation and paralytic poliomyelitis. Similar experience in this country has now been reported by Dr. Dennis Geffen, medical officer of health for the London borough of St. Pancras,[1] and his data show that, even in a single metropolitan borough, the onset of paralytic poliomyelitis in an arm previously injected with pertussis vaccine or alum-precipitated toxoid (A.P.T.) is not extremely rare. In St. Pancras since June, 1949, there have been 19 confirmed cases of poliomyelitis or polioencephalitis in children under five years of age, and in 6 of these cases paralysis has ensued within 14–22 days of the injection of a combined whooping-cough and diphtheria vaccine. As Geffen points out, this experience is not confined to the combined vaccine; in Fulham, for example, the injection of A.P.T. alone into the left deltoid was followed in 4 cases by paralysis of the upper arm. Indeed, the possibility that paralysis follows trauma in its general sense rather than the use of any specific antigen is suggested by the onset of paralysis of the gluteal muscles in one of these inoculated patients who had also received an intramuscular injection of penicillin in the course of treatment for an intercurrent tonsillitis.

In St. Pancras, the antigens used came from different batches and were given by two different doctors who both used different needles for each inoculation. In London as a whole, though there are local differences in the antigens used, the general picture of association between injections and paralysis holds: of the 182 notified cases of poliomyelitis under the age of five, 35 gave a history of inoculation in the four-week period before the onset of paralysis in the injected limb. In 21 of these a combined vaccine was used; in 8 cases A.P.T. was injected; and in 1 whooping-cough vaccine alone was given. The administrative decision following these findings enforced the postponement of the immunisation campaign during the epidemic summer months; but, as we have already said, we must have more facts if we are to strike a balance between the risks of failure to immunise against a disease like diphtheria (which used to cause over 2000 deaths a year before the present campaign started) and the risks of paralysis among children inoculated during an epidemic period.

RESEARCH INTO PRESCRIPTIONS

THE prescription pricing bureaux are still overwhelmed with work, as is testified by the six-month delay before pharmacists receive final payments and by the continuing use of the expedient of averaging the cost of prescriptions under 5*s*. Perhaps because the bureaux are overtaxed with routine work, the Ministry of Health is setting up a special unit whose main function will be to investigate cases of allegedly extravagant prescribing. In such a case the unit will examine the prescribing habits of the practitioner in relation to those of neighbouring doctors, and if it is considered that extravagance is proved, the local executive council will be informed. Perhaps this unit will also be able to study some further questions that need answering. How much, for example, does the practice of ordering proprietary substances vary from one practice, or one district, to another? How great is the variation in prescriptions for dangerous drugs? And is it possible to establish, under present-day conditions, more exact criteria for extravagant prescribing? An affirmative answer to this last question would prevent many doubts and disputes.

SIR HENRY DALE, O.M., has been appointed as adviser to the B.B.C. on scientific programmes for one year beginning on July 1. He will advise on the coördination and content of broadcasts on science and on the choice of speakers and topics. He will also examine the possibilities of developing scientific programmes in television.

AGREEMENTS have been signed by the World Health Organisation with the governments of Czechoslovakia, Denmark, and Poland, to establish in the three countries medical training centres where international courses will be sponsored by W.H.O. In May training centres in anæsthesiology will be opened at Copenhagen and Prague where physicians from neighbouring countries may hold W.H.O. fellowships. There are also to be a training centre in biochemistry at Wroclaw and a training centre in venereal-disease control in Warsaw.

---

[1] *Med. Offr.* April 8, p. 137.

a thorough physical and medical overhaul it is here that, in private, they meet the doctors. It is here that the family comes to know about itself, and to learn how, within its capacity, to make use of the knowledge which science can give to it. The doctors are also brought into close touch with the mind of each individual. There are many aspects to the family consultation procedure and it is precisely the way in which this consultation brings together these various components which give it a unique character.

In the first place the consultation is the point where therapy and enlargement of the personality meet. On the one hand, knowledge of the self opens up the possibility of preventing recurrent illness. On the other, this knowledge may show the individual that it is within his power to enlarge the scope and varity of his own life. In both directions there is the incentive of a wide choice of recreational activities, backing up the process started by an enhanced awareness of what is possible to him. This is the clue to the design of the building in which the centre is housed, and the reason why it is a recreational centre.

Psychologists and sociologists are now aware that a change in individual behaviour is closely related to, and often dependent on, changes in the environment. (Psychotherapy sometimes uses this method by placing a person in a different job, and we may all profit by a change of atmosphere.) In the social sphere the dependence of one person's behaviour on that of another is much greater than we are usually aware of. The less a man is conscious of his social relations the more decisive is this interdependence in the control of his behaviour. Moreover, psychology teaches us that our behaviour towards other individuals is the most inflexible part of our character. Unless therefore a change can be wrought in our relations with our intimate acquaintances, the whole character structure will remain inflexible. Therefore the founders quite rightly made it a condition of membership that member families must be prepared to consider, in consultation with the doctors, the full implications (not the details) of the medical and physiological examinations. In this way individual and reciprocal attitudes within the family were revealed to all the members when the results of the medical overhaul were being discussed.

APPLICATION

Now let us see how the health centre sets about this. It must at once be admitted that technically the scientific investigations were mismanaged owing to a preoccupation with techniques whose validity had not previously been tested. This has meant that modern scientific techniques have found no place in the investigations, and the validity of the centre's results can justifiably be questioned on purely technical grounds. When to this is added an inability to collaborate with scientists in other branches of knowledge, it should be plain why the results of the physiological investigation have not found their place in scientific literature.

In these circumstances the scientific work itself has not demonstrated anything that was not already known; nor have methods been used that are essentially different from the routine medical overhauls carried out in the Army or at school. The novelty lay in applying these methods in a recreation centre where the interaction of social behaviour and recreation upon the psychology and physiology of the individual could be studied. It has been a very expensive way of putting forward this idea. Nevertheless the idea is important and it has been shown that it is quite feasible to obtain continuous records from people from birth to death provided people are given the opportunity of belonging to such a centre.

This has obviously immense potentialities. As we have seen, in Peckham it was possible to relate group social activity to physiological health. Such a concept is not new in itself, since psychosomatic medicine had already illustrated and classified this type of relationship. Nevertheless, the findings of the Peckham Health Centre, in individual instances, have, I think, provided a prima-facie case for the dependence of some quite marked physiological disturbances on relatively mild intrafamilial psychological tensions. They have found that these can be rectified on people's own initiative, provided the information about the state of affairs is given to them. There is no doubt that this method—i.e., obtaining the coöperation of the individual in his own cure and making this potentially dependent on his will—is the aspect of their work which appeals to the non-specialist and members of the general public in particular, and I myself share the valuation placed on it by this wide public. It does moreover link very closely with the concept that the recreational activities which spring from a person's own creative faculty are closely linked with the strength of his will to recover health. In so far as knowledge is a prerequisite of such recovery in their system, the cycle of social activity is an essentially progressive one to which scientists could readily subscribe.

The difficulty scientists find in assessing the value of this type of work is that action and interaction are continually at work, making precise observation very difficult; but this is the real challenge that Peckham holds out to the social investigator. Various schools of sociology in America are already thinking about the problem, but admittedly they do not seem to have got very far.

The fact that the centre fell short of its aim is a great pity; and its shortcomings must be partly ascribed to the arbitrary methods of administration which the founders were unfortunately unable to do without. Inevitably, numbers of other social causes became associated with it, such as the importance of food grown on compost, which after all is quite another matter, but in the minds of those running the centre they were inexplicably interfused not to say confused.

LIMITATIONS ON ACTIVITY

Many investigators who came to the Peckham Health Centre asked where the discipline was, and they always received the answer that there was no discipline. If by this was meant that there were no principles by which people could understand what the limits of their freedom were, this statement is true. But members had only to try something that was disapproved of to find that definite limits were in fact set to social activity. This of course must have been the case, and I suppose the incentive to be a little bit more bold was that much increased by the absence of a prominent set of rules. This in itself might have been, and probably was to some extent, a good element; but the arbitrariness with which on occasions the staff interfered with the activities of the members was startling. Naturally, this need not in other similar experiments be the same. It is clear, however, that lacking serious and frank discussion it has been impossible to find out how to make sociological observations in these circumstances, nor have sociologists been asked to help. Just as there were no obvious limits placed on any particular type of activity by the presence of furniture and equipment designed for specific purposes, so the apparent absence of social *mores* gave an illusionary appearance of an increased social mobility. In fact, however, the social *mores* of the centre were essentially those of the Christian world outside it.

Finally, it is important to remember the relative absence of intellectual and cultural activity which must have struck anyone who stayed there longer than a day. Culture is the expression of accumulated social experience of individuals and incorporates the knowledge of how

To me the ideal training for the practitioner is this. Having obtained his academic degree or diploma he should concentrate on the following:

1. Disease of children, to a high standard.
2. Midwifery, to a high standard.
3. Elementary psychology, the effects of the emotions on the individual, and the organic changes they produce.
4. Disease of the skin.
5. Infectious diseases.
6. Geriatrics.
7. The treatment of incurable diseases.
8. The acute abdomen. Indeed the potential disasters here far outweigh, in my opinion, the acute conditions elsewhere, because elsewhere "a waiting time" is not only common but advisable.
9. Minor maladies and their treatment. Far more satisfaction is given to the patient by their quick and successful treatment than the most heroically successful "ectomy."
10. Human anatomy. The structure of man has not changed for thousands of years; and it is a tragedy that so many doctors, ten years after qualifying, have forgotten their basic anatomy. A good car mechanic has to know all cars, but we only one body. (This is really not a good analogy, but it will suffice for what I want to drive home.) I have yet to meet the doctor who knows his anatomy and is not a good doctor. The good surgeon is the good physician. But what is happening today?—the preclinical stage is being cut! It is just too sad, and to me only reflects the gross error of those who draw up the curriculum; but we must forgive them—they know not—they have never been in general practice.

Medicine is an art, so why should it not be taught a little by the artists rather than almost entirely by the men of science? I would hand to every person on qualifying a handsome book, and it would be a trilogy of *Counsels and Ideals*, *Religio Medici*, and *Rest and Pain*. They live for ever.

Osler—come back—come soon—come quick.

WHERE FROM PECKHAM?

M. R. A. Chance
Ph.D.
BIRMINGHAM

The closing of the Pioneer Health Centre in Peckham comes as a shock to many sympathetic and interested people.

In the last decade this social experiment had become world-famous. It was one to which visitors from abroad were often directed from official quarters. Within recent years it had received publicity not only through articles in the press but also through a Ministry of Information film costing the Government £10,000. A week before the announcement of its closure the centre was being televised.

All this would lead one to believe that it was not only a place of interest to sociologists, but also so successful a venture that many people of diverse interests could be assisted by its work. We may ask therefore how has it come about that the centre is now to be closed?

It is the more necessary to seek the answer to this question since the value of the centre's work has been a subject of controversy for a long time. Scientists were quick to realise that the reporting of the scientific work lacked the standard of accuracy expected in scientific investigation, and most of them have therefore dismissed it as unworthy of further consideration. On the other hand it has continued to attract the attention of progressively minded scientists, and of administrators and social workers throughout the world. In fact it has never lacked the support of prominent people, well known for their achievements in medicine or science.

I was a member of the staff of the Pioneer Health Centre, in an advisory capacity, for some three or four months, and what follows is based on experience immediately before, during, and after that term of employment. There were excellent opportunities for discussing the nature of the work, not only with those primarily responsible for it, but also with many visitors, including some from distant countries. Over and over again one found that though the visitors arrived full of enthusiasm, they left entirely mystified, unable to take back to their friends any clear idea of what was being done. This was a most disappointing experience, and I still fear that the achievements of the centre, and the ideas developed there, will be lost for future generations unless some attempt is made to put forward a statement which could be a basis for discussing future endeavours.

Elsewhere[1] I have pointed out that the achievement of the Peckham Health Centre has two separate aspects. On one hand it appears to have a value as a unique form of social centre based exclusively on family membership; on the other, it was valuable in offering opportunities of scientific investigation of a normal population, made possible by this type of recruitment. In addition we ought now to consider the ideas behind the experiment—ideas which, through the director and his immediate assistants, guided the day-to-day administration of the centre.

We are therefore concerned with *attempting to assess*:

1. What was actually done?
2. What was new about this?
3. What was actually found in the investigations?

We also want to know what is the relation of these things to our knowledge of human society and also to the theory on which the founders interpreted their findings.

THE IDEA

What the founders did was to build a family recreation club of an original design. Their desire was to study the potentialities of this type of recreation for the health of the family. This desire arose from their belief, common to all reformers of the last century, that the health of the population was being impaired by the physical conditions of life in industrial towns. Their unique contribution was the suggestion that the evil results of these conditions were largely due to restriction of opportunities of normal recreation on social behaviour.

This idea was original. Since it contained several components which were essentially biological in origin—e.g., that social behaviour is important, that the unit of study should be the family and not only the individual, and that such a study requires a special environment—it can be regarded as the first serious attempt to found sociological work upon a biological basis. The interaction between social behaviour and health in the individual could, so the founders maintained, be studied by repeated medical and physiological examinations of the members of the centre and by observation of the changes in their social behaviour.

In all human activities, however, there is always an interaction to be reckoned with, between the insight gained through a particular activity and the further direction of this activity. This was especially to be looked for in this instance, since the founders held that the physiological and medical examinations were both scientific and therapeutic in purpose. In fact they took a bold step towards recognising such an *interaction* by introducing the family consultation which put the members in possession of whatever information the centre had obtained about them.

I am convinced that these consultations should be the focal point of attention. After the members have had

In England Now

A Running Commentary by Peripatetic Correspondents

THE hospital management committee has just sent me this note: "Mr. X will, after April 1, 1950, be in attendance at the outpatient clinic of PQR (our local) Hospital each Tuesday at 1.30 P.M. to see cases of backache only."

What will happen? Everybody will first be X-rayed from top to toe on the grounds that they "c/o backache." The women will then be referred to the gynæcological O.Ps. to exclude pelvic pathology" and the men to the venereologist "to exclude prostatitis." After this everyone will be sent to the dentist "? root sepsis" and they will all lose a few ounces of blood for a full blood-count, W.R., G.C.F.T., full Widal, alkaline phosphatase, and blood-urea.

Mr. X will then see the patients. A few will be directed to the chiropodist and will not return to the backache queue for a few weeks. Of the rest, those under 40 will be ordered an E.E.G. and those over 40 an E.C.G. All buxom flatulent women of 40 with two or more children will be ordered a Graham's test; 20–30% of these will "fail to fill" and be referred to Mr. Y, and unless I hear about it in time to put a spoke in Mr. Y's wheel they will ultimately turn up in my surgery, looking even paler and more tired than usual, without their gall-bladders, each with a note requesting me to "dress the small sinus in their operation wound until it heals and refer them back to Mr. Y's O.Ps. in 3/12." Any so stupid as to have "opacities in the lung fields" will be routed back to my surgery bearing "N.A.D." notes, those over 35 coming via the bronchoscopists and those under 35 via the tuberculosis officer.

Mr. Y himself will send most of the remainder back to me in due course. His secretary will write out the long list of negative investigations, to which Mr. Y will add a very sloppy history, a few clinical findings which I know already, and a diagnosis. For people under 45 his diagnosis will usually be "Spinal Arthritis of the Rheumatoid Type," and for those over 45 ditto "of the Osteoid Type. By way of variety he will call about 5% of cases "Whosit's Disease" or "Whatshisname's Syndrome." He will recommend alternate cases "rest preferably in bed," and "light remedial exercises," with an occasional "lighter employment" or "semirigid spinal brace." Then, just to kid us that he has a sense of humour he will order everyone a course of either "infra-red therapy," "ultraviolet light" or "short-wave diathermy," despite the fact that the physiotherapy department is booked up 8 months ahead.

* * *

He was a little Cockney of 32, looking as if he had all the cares of the world on his shoulders and seldom got a night's sleep. He surveyed sister, the X-ray tube, the shining array of syringes and bottles and nozzles, and especially me, with a silent glowering mistrust. I explained that a bronchogram was quite painless; he would feel nothing but a tickle in the back of his throat. He was mollified enough by this to take his Dessicaine lozenge, but after sucking it for a minute his mistrust returned and he grimaced fearfully as he croaked: "It's freezing me froat, guv'nor, an' I can't talk proper." I tried more reassurance, and suddenly his expression changed. A smile crossed his face like a patch of sunlight on the hillside on a cloudy April day, and in a hoarse but urgent whisper he asked: "Got a few o' them tablets to spare?" "What on earth . . . ?" I began, but he went on wistfully: "If I could 'ave a few for me muvva-in-law, doctor . . ."

* * *

When I was a medical student, there were two schools of thought about Truby King. My chief was a devoted disciple, his deputy a rabid opponent. The truth, as I now know, was simply that in his eighth decade Truby King's mind became rigid and fixed, and those who heard him speak found little difficulty in pulling holes in his argument.

Yet for a life of satisfying achievement, Truby King's would be hard to beat. Sceptics have attributed New Zealand's health to its dairy-farms and climate. But when Truby King started his work the infant death-rate in Dunedin was 80 per thousand. In five years, long before the days of family allowances, it had been halved. In 1946, the rate for the whole of New Zealand was down to 25. Truby King started his work in a mental hospital, and it was only in 1920, at the age of 58, that he gave up his post as superintendent of Seacliff Mental Hospital to become Director of Child Welfare for the Dominion. His views on the care of babies developed out of his work among the livestock of the hospital farm, plus a lively belief in the possibility of preventing mental illness by the proper upbringing of children. Of course he had to fight the doctors—but what reformer has not had to? He spent the money he made, like water, to found his first babies' hospital on the beautiful Karitane peninsula, to publish his pamphlets, to help to found and develop the Plunket Society—the backbone of the whole mothercraft movement in New Zealand. On his death, his estate was declared bankrupt, though eventually his few creditors were repaid 20*s*. in the £1. His story, as it has now been written by his adopted daughter, Mary King,[1] proves that bankruptcy is sometimes well worth while. Miss King's book stimulates that gnawing longing to see those beautiful sensible islands on the other side of the world.

* * *

The Rugby game between England and Scotland this year was such an epic performance that Rex Alston and his brother canaries in the broadcasting box, excellent as their account was, really needed the assistance of a poet. I would like to see the 1951 game for the Calcutta Cup reported more like this:

. . . Like maddened kine the mud-stained forwards plunge.
Ah, now the ball is loose—from Smith to Brown,
who sells the dummy—now to Robinson,
whose feet the touch-line swiftly parallel.
But see, MacSpeer, the Scottish back doth streak
like some dark missile to the corner flag,
which idly flaps its pennant, unaware
that here's the trysting-place of supermen.
A silence falls, only the thud of feet
is heard like pin-drops in the Albert Hall.
Terrific dive! MacSpeer has caught the heels
of England's fleetest, and the corner flag
is mixed with rolling bodies on the ground
Now eighty thousand faces gape to let
the steam of their emotions rend the sky.
Line out,—

Scrum before the English goal. What now?
The whistle goes—some warrior is hurt;
they gather round in tenderness—ah, no!
MacSporran's lost his shorts!

Like northern combers now the Scottish pack
surges towards the thin-held English line,
growling strange oaths and Highland diatribes,
until J. Doe, the English scrum-half, curls
himself, a question-mark, around the ball,
a kicked impediment. The whistle goes;
he hath outstayed his asking.

What means that piercing blast? Ah, lemon time.
Sweet lemon time. I'll hand you back to Rex.

A try! A try! A glorious sort of try!
With sinews strained to snapping point Smith swerved
—"That's Smith, that was," the Scotchmen might have said—
and like a scalded cat he lineward streaked
to place the ball between the towering poles
that seem to sway in gusts of acclamation.

And now amid melodious cheers there rasps
the final screech, the multitude is up,
and $\left\{\begin{matrix}\text{Scotland}\\\text{England}\end{matrix}\right\}$ to her muddy bosom clasps
the Calcutta Cup.

Well, perhaps the B.B.C will ask me after seeing my samples.

previously individuals have been able successfully to approach different types of problems. As Norman Cameron says: "Life's complexities seem always to exceed our immediate competence. Need and desire keep ever ahead of our behavioural resources as well as our economic ones."

The centre was thus lacking in an essential social activity peculiar to humans, and in this sense it was biologically inadequate to its task. This deficiency must have been a major factor which made the centre so incomprehensible and at the same time so unsatisfactory to those administrative and social workers who wished to learn from it.

The centre is now closed, but it is to be hoped that the ideas which underlie this conception will one day be put to a searching though sympathetic test.

Public Health

Smallpox in Glasgow

AN Asian seaman, aged 38, was admitted to Knightswood Hospital, Glasgow, on March 10, as a case of pneumonia; and on March 13 he was transferred to a cubicle as probable chickenpox. He had been previously well vaccinated. On March 23 he was discharged well from Knightswood Hospital to the Indian seamen's hostel.

This seaman, as recorded in our last issue, had landed from the S.S. *Chitral* at Tilbury on March 5. The ship had a clean bill of health, and the appearance of smallpox on March 25 among the nursing staff at Knightswood Hospital was the first indication of the true nature of his illness—namely, much-modified smallpox.

Up to last Tuesday there had been 20 secondary cases with 6 deaths—1 from hæmorrhagic smallpox, 4 from confluent smallpox, and 1 of a baby (aged ten months), who also suffered from toxoplasmosis. Of the cases, 8 arose among the nurses (full-time or part-time) who had been in direct contact with the infected seaman, and 3 of these have died. Another fatal case was in a laundry-maid who handled the bedclothes from the original patient. Most of those who died were unvaccinated or had an unsatisfactory history of vaccination.

Up to Tuesday the outbreak had been entirely confined to direct contacts with this Asian seaman in the hospital. In the absence of any further cases arising from contact with the secondary cases, Glasgow will be clear of smallpox by April 17. Approximately 300,000 persons in the Glasgow area have now been vaccinated, including 170,000 by the public-health department's own clinics.

Medicine and the Law

Inquests in Private

AT an inquest in Yorkshire on March 25, held in a room in the house of the deceased, the coroner excluded representatives of the press. He afterwards described the proceedings to three reporters who had sought admission. It was, he explained, within his discretion to deal with the press as he wished; in cases of that kind relatives would speak more freely if reporters were not present.

There is no doubt that the coroner was legally justified in this action. In the leading case of Garnett *v.* Ferrand (1827) Garnett was turned out of the room by the coroner, though there was plenty of space for him; he had not been summoned to the inquest, was not in any way under suspicion in respect of the death, and was not a relative of the deceased or even an inhabitant of the place in which the body had been found. He had, said Lord Tenterden, C.J., no interest in the matter of the inquest and no information to offer.

> "It was admitted in the argument that secrecy and exclusion may be proper and necessary when charge and accusation begin. It is obvious that this may begin as soon as the evidence may begin. Cases also may occur in which privacy may be requisite for the sake of decency, others in which it may be due to the family of the deceased. Many things must be disclosed to them who are to decide, the publication whereof, to the world at large, may be productive of mischief without any possibility of good. Who then is to decide whether privacy be necessary or proper? We answer, the coroner and the coroner alone, and that the propriety of the decision cannot be questioned in an action."

Lord Tenterden summed up his views by declaring that "the power of exclusion is necessary to the administration of justice," in which connection it may be recalled that section 19 of the Indictable Offences Act, 1848, authorises the examining justices to sit in private "if it appear to him or them that the ends of justice will be best answered by so doing."

The layman, associating all legal procedure with a sitting in open court, may feel some surprise at this tolerance of secrecy. During 1933 the Leeds coroner, criticised by the press for holding an inquest in private, replied that he had held 83 such inquests in 1932, whereupon the newspaper rejoined that this showed that the office of coroner ought to be abolished. The departmental committee on coroners over which Lord Wright presided in 1935 were content to observe that inquests were "almost invariably" held in public. Their report referred respectfully to the ruling in Garnett *v.* Ferrand that "for special reasons—e.g., in the interests of justice, decency, order or even from a consideration of what is due to the family of the deceased—the coroner may hold the whole or part of an inquest in private." There the matter remains, though in 1938 Lord Atkin, addressing the Coroners Society, expressed misgivings. He had noticed with surprise, he said, in the case of accidents on railways or in the course of air travel that at a certain stage whoever was conducting the inquiry announced that he intended to take the remainder of the inquiry in private. Lord Atkin thought that was not right; the public were interested in ascertaining the reasons and the responsibility for the accident; he hoped sincerely that coroners would conduct the whole of their inquiries in public and have the whole of the facts disclosed.

The coroners doubtless took note of an opinion proceeding from so high an authority. As, however, Parliament has made no permanent change in the law of coroners and inquests since 1926, the country may be supposed to be satisfied with the status quo.

Letters to the Editor

THE CARNAGE ON THE ROADS

SIR,—Surely it is time that someone pointed out that most widely perpetuated, longest neglected, most easily explained, and least considered anomaly of all. It is to do with night driving. It is simply that all the lights on a vehicle point the wrong way.

The sidelights of a car are direct descendants of the candle in a glass box. No-one has ever reconsidered their function. They are too feeble to illuminate the road in front, but their direct rays are quite bright enough to dazzle the oncoming motorist. By official circles they are happily supposed to indicate the position of a vehicle to which they are attached. The headlights are the boon conferred by electricity and optics upon the dazzled motorist to shatter the wall of darkness advancing behind his opponent's sidelights. They work well until the opponent switches on *his* headlights. A pair of approaching motorists have the choice of dazzling each other with equally bright lights or with equally feeble lights. Whichever they choose, the equipment, so disposed as always to send a direct ray into the other man's eyes, is perfectly arranged to dazzle. Behind and around the dazzling source of light is that advancing wall of darkness.

In a sensible world all the lamps would be pointed differently—almost any way would be better than the way we have them at present. The sidelamps would be twisted round to point backwards to illuminate the wings and radiator. Then the bewildered pedestrian would at last cease worrying as to whether the two lights he sees are far apart and a long way away or near together and close to, and whether their progressive separation signifies high-speed approach or merely two cyclists. He would for the first time be able to recognise a car at night as he recognises it by day, by seeing it, and thereby be able to judge where it is and what it is doing. The rear light would be directed forwards to flood the back of the car. It could be any colour to taste, red if you wish, so long as it serves to reveal a *car* and not a red disc devoid of almost any property by which its distance away might be judged. The near-side headlight in the dipped position would be screened so as to be invisible to the oncoming motorist (by means of a "venetian blind" mask or by being set back behind and below the bonnet), and the offside headlight would point sideways to the right, so as to illuminate, for the benefit of the other fellow, the area behind the wall of darkness. (He would do the same for you.) In the undipped position anything you like can be switched on. Anything else revolutionary? Oh yes. The interior light may be left on for choice—a bus is one of the easiest vehicles to miss.

The rules throughout are, "no rays from a lamp should ever fall on a driver's eyes" and "we see things by the light they reflect." The elements of illumination are just being appreciated by the folk who floodlight their buildings.

Could this possibly be achieved? Of course not. It requires us to do something for the other fellow, and this is a characteristic foreign to our nature. Also the neat symmetrical appearance of our cars would be upset; the bodywork designers would have to make serious alterations; and no-one with a dollar to spend would buy such a crazy car. Otherwise I would have patented the system long ago.

SURGEON.

SIR,—It is to be hoped that many doctors will agree with Dr. Clausen (April 1) that the prevention of road accidents is worthy of the interest of the medical profession. It would, however, be unfortunate if THE LANCET were to encourage indiscriminate denunciation of the motorist, or to spread the myth that there are separate classes of road-users, each condemned to wage bloody or verbal war on the others.

Drivers are also pedestrians and so are their children, while many have been cyclists and motor-cyclists. Most pedestrians and cyclists would like to drive a car and some will later do so. All should consider the problems of their fellow road-users, because they are also their own problems; but all at times fail. No doubt the duty of showing consideration falls most heavily upon the driver, but it is hardly correct to accuse motorists or the "motoring interests" of carrying out an anti-safety campaign. Accidents are certainly not beneficial to drivers.

In his interesting article (Feb. 25), Dr. Learoyd rightly emphasises the number of children killed and the importance of educating children and parents in road safety, but characterises the driver as "the person who does the killing" and recommends strict training of drivers. This is perhaps an over-simplification, for it takes no account of the wider social and economic causes of road accidents; for instance, if towns were better planned, housing less inadequate, and housewives less hard-pressed, there would be few young children unattended on busy streets.

Dr. Learoyd blames the A.A. and the R.A.C. for opposing the present driving test as being of very doubtful practical utility, but devotes much space to criticising it, by implication, for the same reason. A comprehensive course of instruction, with searching examinations and psychological tests, such as he advocates for motorists and motor-cyclists, may, in principle, be the ideal requirement for many sections of the community who in one way or another are responsible for the safety of others. The difficulties in each case are economic and administrative. Moreover, irrevocable disqualification from driving on psychological or medical grounds would have to be subject to appeal to the courts, whose present attitude towards psychologists' evidence makes it unlikely that they would readily uphold the doctrine of "accident-proneness," true though we may believe it to be.

It appears that, for the present, education of the public must continue to be the main weapon against road accidents.

Is the road-safety campaign gathering momentum as rapidly as it should? How many of your readers, for instance, are constantly aware of it as a helpful influence in their multiple rôles as parents, pedestrians, motorists, and so on?

Finally, can the medical profession do more to help, by providing material for education through those "instructed asides" to which Dr. Learoyd refers, by establishing more firmly the objective criteria of fitness to drive, and in other ways?

London, S.E.26. C. D. L. LYCETT.

HYPERTENSION

SIR,—Recent views and practice in the treatment of hypertension were summarised in your leading article of March 25.

For many years I have been accustomed to prescribe for these patients an empirical remedy which is successful in a fair proportion of cases. It is simple enough, consisting of 10 minims of dilute hydrochloric acid given four times daily, between meals. After three weeks, in the successful case, the systolic pressure will be found to have dropped appreciably, and often also the diastolic. The patient is usually well aware of the change and reverts to the acid whenever he feels that the pressure is rising.

Work on experimental nephrosclerosis by Selye, Hall, and Rowley[1] has given a rational explanation of the benefit derived from this medication. Groups of rats, unilaterally nephrectomised, treated with adrenal-cortex compounds, developed nephrosclerosis and died. If ammonium chloride was incorporated in the water imbibed by these rats, then they remained healthy. This salt is a combination of urea and hydrochloric acid.

London, W.1. H. WARREN CROWE.

UNSUCCESSFUL TREATMENT OF TYPHOID FEVER WITH CHLORAMPHENICOL

SIR,—Typhoid fever is more or less endemic in this part of Africa. Cases are rarely associated with definite outbreaks, but the incidence is higher during the wet months from November to March. The vast majority of cases are mild clinically, and the patients usually recover, without complications, on conservative treatment. However, there do occasionally occur extremely severe attacks more akin to the classical typhoid picture; these cases invariably yield a strain of *Salmonella typhi* rich in Vi antigen, and their prognosis is, on the whole, poor. It was in such a case that chloramphenicol was first used in this hospital.

An African boy, aged 7 years, was admitted on Feb. 10, 1950. His parents, who were intelligent and coöperative, said he had been taken ill suddenly two days before with fever and diarrhœa, having previously been perfectly well.

On admission the boy's temperature was 105·6°F and pulse-rate 128 per min. He was semi-delirious but said he had a bad headache and colicky abdominal pain. His general condition showed moderate toxæmia without appreciable dehydration. There was generalised tenderness over the whole abdomen, with no rigidity, and the spleen was felt 2 finger-breadths below the costal margin. The stool was watery, of normal colour, and contained no blood. Treatment with quinine and sulphaguanidine was started.

Progress.—On his fourth day in hospital (sixth day of disease), there being no improvement in his condition apart from cessation of the diarrhœa, the possibility of typhoid was considered, and a blood-culture was made. The quinine and sulphaguanidine were stopped. Three days later (ninth day of disease) the culture was reported to have grown *S. typhi* rich in Vi antigen. By this time the child was extremely toxic. Chloramphenicol was begun, an *initial* dose of 1·5 g. being followed by 0·25 g. two-hourly (3 g. daily). There was no vomiting, and within twelve hours the boy's temperature began to fall more rapidly and his general condition seemed much improved. By the morning of the third day of treatment (eleventh day of disease) his temperature had fallen to 98·2°F and his general condition appeared good, though he was very weak. After midday, his condition began to deteriorate rapidly; his temperature rose to 99·4°F, his pulse was feeble, rate 150 per min., and restlessness returned. During the evening he remained in a collapsed state, and he died early next morning (twelfth day of disease), after receiving a total of 7·5 g. of chloramphenicol.

Necropsy showed numerous typhoid lesions in the jejunum and ileum but no evidence of intestinal hæmorrhage or perforation. The heart muscle was pale, soft, and friable. Death was ascribed to acute toxæmia due to typhoid fever.

The dosage of chloramphenicol recommended for children is 100 mg. per kg. of body-weight as an initial dose, followed by 100 mg. per kg. daily in divided doses. This child weighed 62 lb. (28 kg. to the nearest kg.). The recommended initial and daily maintenance doses would therefore have been 2·8 g. Cook and Marmion,[1] however, have shown that high initial doses of chloramphenicol are not tolerated by very toxic patients, and are often vomited. It was therefore decided to halve the initial dose but to keep the maintenance dose at about the recommended level. The doses were given two-hourly to lessen the risk of vomiting, and there was no evidence of gastric intolerance.

The sudden collapse after such striking improvement is difficult to explain. It may be that a reaction similar to the Jarisch-Herxheimer reaction in syphilis took place. On this supposition, when the chloramphenicol began to take effect, endotoxins were suddenly released from the virulent strain of *S. typhi*. The resultant toxæmia might well overwhelm the resistance of an already weakened patient. The necropsy findings do not conflict with this view.

One should perhaps conclude that special care must be taken in treating cases caused by virulent strains of *S. typhi*. The chemotherapeutic attack must be powerful enough to hold the organisms in check and then destroy them, but not so powerful as to release endotoxins at a rate greater than the body can stand. The optimum dosage can only be established after considerably more experience with chloramphenicol.

I wish to thank the Director of Medical Services, Northern Rhodesia, for allowing chloramphenicol for this case and for permission to publish this report.

African Hospital, Lusaka,
Northern Rhodesia.
P. R. STEPHENS.

STERILISATION OF SYRINGES

SIR,—May I comment as follows on Dr. Barnett Mallinson's letter in your issue of April 1?

1. The support adduced for the implication that oil at 120–130°C rapidly drawn into a syringe, swilled round, and expelled, several times, does sterilise the interior of the syringe, by reference to the description of such a method in M.R.C. War Memo. no. 6, 1942, omits mention of the fact that M.R.C. War Memo. no. 15, 1945, rejected this method, stating that it "has been tested . . . and has been found unsatisfactory for sterilizing syringes. Even vegetative organisms dried on to the glass are not uniformly destroyed."

2. The "layer of superheated steam" which "presumably . . . is the most effective sterilising factor" would, with oil in the reservoir at the temperature range stated, hardly exceed an average temperature of, say, 120°C—i.e., approximately that attained in autoclaving at 15 lb. pressure. The effective exposure would hardly exceed 1 minute; but Dr. Mallinson states that 15 minutes are needed to achieve sterility, and War Memos. nos. 6 and 15 say 20 minutes.

3. In so far as reliance is placed on the hot oil itself (and this would obtain, perhaps, for the needles placed in it "for $^1/_2$–1 minute," since they would not be evenly wetted by water however well rinsed) the process must be regarded as equivalent to sterilisation by dry heat.[1] For this, however, 60 minutes and 160°C are stated to be required to ensure true sterility.

4. The method described can only be used for procedures where the inevitable small amount of remnant "contamination" of syringe and needle is permissible. The kind of oil used is not stated—but even liquid paraffin *B.P.* rapidly deteriorates below *B.P.* standard when heated with access of air. The apparatus illustrated by Dr. Mallinson appears to provide a relatively large oil/air interface per volume, and the factor of air access would be increased by the manipulations. It would seem to be implied by the existence of the very stringent *B.P.* "Acid Test" that whatever substances develop in heated oil, causing it to fail this test, are undesirable as constituents of an injection.

As Dr. Mallinson points out, the importance of satisfactory sterilisation of syringes is a real source of worry. M.R.C. War Memo. no. 15 described techniques which seem to be either too cumbersome, or demanding of special equipment and too much attention to minutiæ of procedure, to be readily accepted by most practitioners.

I wish it could be a contribution to a solution of this problem to draw attention to the method of sterilisation developed by Foster,[2] who took advantage of the fact, confirmed by Prof. L. P. Garrod, that addition of 2% of sodium carbonate to boiling water secures death of *all* organisms in 5 minutes' boiling. Investigating the extension of this method to dental instruments (including syringes) Harvey[3] found that the biologically inert surface-active agent added by Foster had also an effective detergent action which increased its usefulness. The inevitable remnant "contamination" does, of course, contain a minute amount of the alkali; but this is stated to have no detectable inactivating effect on local-anæsthetic solutions used in dentistry—indeed it may be advantageous. I believe that further experimentation along these lines—of addition to boiling water (even without alkali, perhaps) of one of the many recently developed synthetic detergents and surface-active agents, some of which have marked antibacterial properties—might lead to a cheap, simple, quick, and universally applicable method of achieving true sterility of injection and aspiration syringes and needles.

"INTENSIVE" INTRAVENOUS ANTITOXIN TREATMENT OF DIPHTHERIA

SIR,—While I have not yet had the pleasure of reading Dr. Stanley Banks's new book *The Common Infectious Diseases*, I feel obliged, "in the interests of historical accuracy," to correct a statement in the final sentence of his letter (April 1), where he claims that in 1928 the routine treatment of hypertoxic cases of diphtheria, except in Copenhagen, was by intramuscular antitoxin. This was certainly not the case while I was a resident medical officer at Plaistow Hospital, under Dr. Donald McIntyre, from 1924 to 1927. The usual treatment of severe cases of diphtheria at that time was by 40,000–50,000 units given intravenously and a similar or larger dose intramuscularly. This dose was often repeated on the following day.

In a disease so variable and complex as diphtheria, I believe that clinical judgment and impressions must count for more than statistics of case-mortality. After a long experience in the treatment of this once-menacing infection, using doses of antitoxin both large and small, I am not convinced that the astronomical doses recommended by Dr. Banks and others are superior to more modest amounts given by the same route. Deaths in diphtheria have been due more to faults in early diagnosis than to underdosage of antitoxin, and it is to this aspect of the disease that we should direct our attention if the disease should ever again assume its former proportions.

VAGOTOMY AND PARTIAL PYLORECTOMY

SIR,—Mr. Beattie must be congratulated on his operation of partial pylorectomy as a supplement to vagotomy, which appears to be a real advance, and on the excellence of his results. His article (March 25) prompts me to comment on the physiological basis for vagotomy.

The mechanism of production of psychogenic ulcers is obscure, but some may find hyperacidity difficult to accept as an entirely satisfactory single explanation. A vascular factor may play an important part. Vascular lesions have been described on stimulation of an area in the cortex (hyperæmia, petechial hæmorrhages, and small ulcers [1]): on stimulation of the hypothalamus (petechial hæmorrhages and hæmorrhagic erosions,[2] and multiple hæmorrhagic erosions [3]); and on stimulation of the vagus (hyperæmia and occasional ulcers [4]). Wolf and Wolff's [5] patient showed hyperæmia and petechial hæmorrhages at times of mental stress.

The matter is not entirely academic, as the vascular hypothesis tends to focus attention upon the rôle of the vagus in the *initiation* of ulcers, and this may point the way to the rational selection of cases for vagotomy. The hyperacidity hypothesis tends to focus attention on the perpetuation of ulcers, for whatever view may be taken of its rôle in initiation, it is generally accepted as the agent responsible in perpetuation. If the importance of vagotomy lies in the *prevention* of ulcer formation, it at once becomes obvious that too much should not be expected of it in the treatment of chronic ulcer. The reduction of acidity will assist natural recuperative powers and medical measures, and will lead to the healing of small chronic ulcers. Its failure in ulcers of any degree of chronicity and attachment to surrounding structures is readily understood. On the other hand, it should be of great benefit, as suggested by Mr. Beattie, in the treatment of patients with recurrent subacute ulcers. I would suggest, too, that patients with recurrent hæmatemeses in whom no radiological lesions are found and in whom the cause is presumably acute erosion, would be similarly benefited. Owing to the similarity in behaviour of prepyloric and duodenal ulcers, I would suggest also that further trial might be given to vagotomy in recurrent subacute and small chronic ulcers in the prepyloric region.

SIR,—With regard to the operation described on April 1 by Mr. Hughes and Mr. Fathi, I recall that some years ago [1] a similar procedure was described by Mr. Percival Cole.

Plymouth. JAMES RIDDELL.

WAR

SIR,—Apparently neither Dr. West nor Dr. Comfort thinks it necessary to search for particular responsibility in the causation of war. Faults on both sides is their theme. If at first sight culpability should seem to be not quite equally shared between contestants they do not hesitate to cast round for something to restore the balance. Evidently they consider that in the recent struggle we were much to blame. "We have already witnessed," says Dr. West, "the destruction of much of our civilisation by men who still lead us." To many it may have seemed at the time that in this destruction leaders other than our own played a more notable part. Dr. West, however, prefers to avoid selective condemnation. Rather does he ascribe all wars to the infirmity of mankind, to those human shortcomings which Grotius judged as ". . . a madness" periodically driving men "to all kinds of crime." We, too, implies Dr. West, "like other lunatics," were lately moved to rave, to wreck, and to kill, believing in our frenzy that there was "no other way."

But, in 1939, was there any other way? It takes two sides to make a fight but only one to start it. Had the Allies not defended themselves there would have been no war. Instead the Germans would by now have established an odious hegemony over the rest of the world. The will to provoke this catastrophe arose in the minds of men. But so indeed did the will to prevent it. Should we chide the defenders equally with their enemies? Or should we not rather be grateful to them?

Nothing is to be gained by self-abasement. The "you're another!" line was always one of Goebbels's favourites. Even several hundred thousand civilians killed by bombs in the exigencies of battle scarcely merit comparison with the policy that condemned twelve million men, women, and children to be asphyxiated in gas-chambers or shot into lime-pits. Neither is the most prejudiced examination of our war leaders likely to reveal a psychopath worthy to rival Hitler.

---

[1] *Brit. med. J.* June 21, 1919.

Dr. West, it would appear, anticipates Orwell's *Nineteen-eighty-four* in contending that were men not besotted by propaganda there would be no cause which they would consider worth fighting for. This is not yet true. Moreover he assumes that a threat of overwhelming force could be offered by an organisation of "power-units" which had abrogated some of their national sovereignty; such a threat would suffice to deter aggression. The assumption is vain unless the threat presented be real. The adherents of the new bloc must still believe that their way of life merits defence with arms. It is illogical, therefore, to deprecate fighting qualities which may yet be vitally needed.

Dr. Comfort is so preoccupied with the avoidance of war that he has lost sight of the greater evil. In his distaste even for the limited coercion necessary for organised self-defence he advocates a course which would render almost inevitable a tyranny infinitely more grievous. Suppose that his philosophy of "rational disobedience," were to gain a wide following in democratic countries while achieving somewhat fewer disciples elsewhere. All recent precedent proclaims that the democracies who refused to fight would be annihilated. Yet it would be better that all life in this island should be obliterated by atomic bombs rather than that a degraded selection of its inhabitants should survive, destroyed in dignity and spirit, under a totalitarian occupation.

To preserve peace, then, there must first be force, manifest and benevolent, ready to deter aggression. Metternich's motto "Force within Law" may be amplified to "Force within World Law."

With aggression rendered impracticable there yet remains to be decided what it is that projects in the minds of men the desire to attack their neighbours. For this communal resolve, it may be granted, is the cause of war. The rôle of the psychopath in office may well increase in the future but this factor has not hitherto been important. Most of the old motives are out of date. The specious Marxian theory of economic necessity can certainly be discounted. In modern times what hopes can be excited by the prospect of war? What is it, for example, that gets into the Germans? Here issue must again be taken with Dr. West.

It was not "we" nor "mankind" nor any universal human infirmity that caused the last three great European wars. Neither was it Hitler who instigated the most recent one. Never in history can a ruler more completely have expressed the temper and purpose of his people than did Hitler in 1941. It was the Germans who caused these wars. Why? The strange truth is that by 1941, when success, admittedly, had exalted their dearest anticipations, every German was fighting to win a little gang of slaves that he could have for his very own. In pursuit of this ideal he was prepared to live on one meal a day indefinitely. Such, in its fullest flowering, was the vision of the German *Weltanschauung*.

Because this aim was monstrous the peoples of the world outside Europe are now largely unable to believe that it existed. By contrast, on the Continent, it is too well understood even to merit discussion. It would be well if comprehension were more general, for only with recognition and acceptance can the menace of such behaviour be dissipated. The German aberration owes nothing to heredity. It is the result of conditioning. New contacts and a changed mental environment, if long enough continued, would effect a cure.

In other nations today impulses of genuine fear may be shaping the minds of men towards "preventive" aggression. No effort should be spared in the attempt to identify and allay such apprehensions. Whatever its origin, however, it is to be hoped that in future the remainder of the world will more readily accept evidence of aggressive intent. For the present it is unwise that Dr. West and Dr. Comfort should seek an end to well-tried loyalties. In doing so they must place in jeopardy the only foundations which as yet offer practical hope for the defence of freedom. In the recent words of Winston Churchill: "How easy it is to impair great unities and how hard to make them."

Bristol. I. McD. G. STEWART.

DANGER FROM THE NEWER INSECTICIDES

SIR,—I have read with interest your annotation of March 4, and the subsequent correspondence. As a layman, may I ask if, apart from any question of humanity, we are wise in using insecticides which, if so dangerous to man, must be death to small birds and the wild animals? Have they no value? Can we live in a desert?

Caterham, Surrey. E. E. RICHARDS.

PELVIC TUBERCULOSIS IN THE FEMALE

SIR,—Your account last week of a meeting of the Edinburgh Obstetrical Society recorded a high mortality in the surgical treatment of pelvic tuberculosis in the female, and ended with the statement that a controlled clinical investigation is urgently required into the effect on this disease of streptomycin and *p*-aminosalicylic acid. There is good reason to believe that an extended study of this problem will be arranged in the near future. In the meantime, we would report, for the encouragement of others, that of the last 6 women with tuberculous endometritis and salpingitis treated in this department with streptomycin alone, 5 have been apparently cured.

The diagnosis was made only when a positive culture from the endometrium was obtained, and apparent cure was assumed only when three consecutive biopsies at monthly intervals yielded negative cultures and no histological evidence of disease. It is too early to state with assurance that the cure is absolute.

In the last ten years, 49 women have been treated by us for pelvic tuberculosis. Prior to the use of streptomycin the only cures were obtained by radical surgery, using the same technique as we adopt for carcinoma of the corpus; 14 patients were treated in this way with no operative and no postoperative deaths and no fistulæ. If the encouraging results so far obtained with streptomycin continue, it may be possible in many cases to both cure the disease and preserve normally functioning organs.

The Radcliffe Infirmary, Oxford. J. A. STALLWORTHY
D. N. STRUAN ROBERTSON.

ANTIGEN-ANTIBODY REACTIONS

SIR,—I was much interested in Dr. Stratton's article of Feb. 11.

The concept of non-specificity was suggested very early. A number of workers have urged me to use Rh-negative hapten as a "control": but I think that the conviction that hapten made from Rh-negative blood is inactive is based on a misconception. The term "Rh-negative" suggests that such blood lacks something; but, of course, thanks to a number of workers, including R. R. Race and R. A. Fisher, we know that this is not the case.

An individual who is Rh-negative (or Hr-positive) carries a factor in his blood which, in all probability, is very closely similar, biochemically speaking, to Rh. From the viewpoint of biochemistry, the difference between D and d may be not greater than the difference between glucose and fructose, or even *d*- and *l*-isomers.

I have made hapten from Rh-negative blood; and I have made other specific haptens from the various subtypes. These I have assayed very carefully. With an anti-D serum one obtains strong reactions with a D antigen, and weaker reactions with a C or an E or a cde surface-active agent added by Foster had also an effective detergent action which increased its usefulness. The inevitable remnant "contamination" does, of course, contain a minute amount of the alkali; but this is stated to have no detectable inactivating effect on local-anæsthetic solutions used in dentistry—indeed it may be advantageous. I believe that further experimentation along these lines—of addition to boiling water (even without alkali, perhaps) of one of the many recently developed synthetic detergents and surface-active agents, some of which have marked antibacterial properties —might lead to a cheap, simple, quick, and universally applicable method of achieving true sterility of injection and aspiration syringes and needles.

London, W.1. C. H. LE MAY.

"INTENSIVE" INTRAVENOUS ANTITOXIN TREATMENT OF DIPHTHERIA

SIR,—While I have not yet had the [illegible] Dr. Stanley Banks's new book *The* [illegible] *Diseases*, I feel obliged, "in the interests of historical accuracy," to correct a statement in the final sentence of his letter (April 1), where he claims that in 1928 the routine treatment of hypertoxic cases of diphtheria, except in Copenhagen, was by intramuscular antitoxin. This was certainly not the case while I was a resident medical officer at Plaistow Hospital, under Dr. Donald McIntyre, from 1924 to 1927. The usual treatment of severe cases of diphtheria at that time was by 40,000–50,000 units given intravenously and a similar or larger dose intramuscularly. This dose was often repeated on the following day.

In a disease so variable and complex as diphtheria, I believe that clinical judgment and impressions must count for more than statistics of case-mortality. After a long experience in the treatment of this once-menacing infection, using doses of antitoxin both large and small, I am not convinced that the astronomical doses recommended by Dr. Banks and others are superior to more modest amounts given by the same route. Deaths in diphtheria have been due more to faults in early diagnosis than to underdosage of antitoxin, and it is to this aspect of the disease that we should direct our attention if the disease should ever again assume its former proportions.

VAGOTOMY AND PARTIAL PYLORECTOMY

SIR,—Mr. Beattie must be congratulated on his operation of partial pylorectomy as a supplement to vagotomy, which appears to be a real advance, and on the excellence of his results. His article (March 25) prompts me to comment on the physiological basis for vagotomy.

The mechanism of production of psychogenic ulcers is obscure, but some may find hyperacidity difficult to accept as an entirely satisfactory single explanation. A vascular factor may play an important part. Vascular lesions have been described on stimulation of an area in the cortex (hyperæmia, petechial hæmorrhages, and small ulcers[1]): on stimulation of the hypothalamus (petechial hæmorrhages and hæmorrhagic erosions,[2] and multiple hæmorrhagic erosions[3]); and on stimulation of the vagus (hyperæmia and occasional ulcers[4]). Wolf and Wolff's[5] patient showed hyperæmia and petechial hæmorrhages at times of mental stress.

The matter is not entirely academic, as the vascular hypothesis tends to focus attention upon the rôle of the vagus in the *initiation* of ulcers, and this may point the way to the rational selection of cases for vagotomy. The hyperacidity hypothesis tends to focus attention on the perpetuation of ulcers, for whatever view may be taken of its rôle in initiation, it is generally accepted as the agent responsible in perpetuation. If the importance of vagotomy lies in the *prevention* of ulcer formation, it at once becomes obvious that too much should not be expected of it in the treatment of chronic ulcer. The reduction of acidity will assist natural recuperative powers and medical measures, and will lead to the healing of small chronic ulcers. Its failure in ulcers of any degree of chronicity and attachment to surrounding structures is readily understood. On the other hand, it should be of great benefit, as suggested by Mr. Beattie, in the treatment of patients with recurrent subacute ulcers. I would suggest, too, that patients with recurrent hæmatemeses in whom no radiological lesions are found and in whom the cause is presumably acute erosion, would be similarly benefited. Owing to the similarity in behaviour of prepyloric and duodenal ulcers, I would suggest also that further trial might be given to vagotomy in recurrent subacute and small chronic ulcers in the prepyloric region.

Rather does he ascribe all wars to the infirmity of mankind, to those human shortcomings which Grotius judged as ". . . a madness" periodically driving men "to all kinds of crime." We, too, implies Dr. West, "like other lunatics," were lately moved to rave, to wreck, and to kill, believing in our frenzy that there was "no other way."

But, in 1939, was there any other way? It takes two sides to make a fight but only one to start it. Had the Allies not defended themselves there would have been no war. Instead the Germans would by now have established an odious hegemony over the rest of the world. The will to provoke this catastrophe arose in the minds of men. But so indeed did the will to prevent it. Should we chide the defenders equally with their enemies? Or should we not rather be grateful to them?

Nothing is to be gained by self-abasement. The "you're another!" line was always one of Goebbels's favourites. Even several hundred thousand civilians killed by bombs in the exigencies of battle scarcely merit comparison with the policy that condemned twelve million men, women, and children to be asphyxiated in gas-chambers or shot into lime-pits. Neither is the most

prejudiced examination of our war leaders likely to reveal a psychopath worthy to rival Hitler.

Dr. West, it would appear, anticipates Orwell's *Nineteen-eighty-four* in contending that were men not besotted by propaganda there would be no cause which they would consider worth fighting for. This is not yet true. Moreover he assumes that a threat of overwhelming force could be offered by an organisation of "power-units" which had abrogated some of their national sovereignty; such a threat would suffice to deter aggression. The assumption is vain unless the threat presented be real. The adherents of the new bloc must still believe that their way of life merits defence with arms. It is illogical, therefore, to deprecate fighting qualities which may yet be vitally needed.

Dr. Comfort is so preoccupied with the avoidance of war that he has lost sight of the greater evil. In his distaste even for the limited coercion necessary for organised self-defence he advocates a course which would render almost inevitable a tyranny infinitely more grievous. Suppose that his philosophy of "rational disobedience," were to gain a wide following in democratic countries while achieving somewhat fewer disciples elsewhere. All recent precedent proclaims that the democracies who refused to fight would be annihilated. Yet it would be better that all life in this island should be obliterated by atomic bombs rather than that a degraded selection of its inhabitants should survive, destroyed in dignity and spirit, under a totalitarian occupation.

To preserve peace, then, there must first be force, manifest and benevolent, ready to deter aggression. Metternich's motto "Force within Law" may be amplified to "Force within World Law."

With aggression rendered impracticable there yet remains to be decided what it is that projects in the minds of men the desire to attack their neighbours. For this communal resolve, it may be granted, is the cause of war. The rôle of the psychopath in office may well increase in the future but this factor has not hitherto been important. Most of the old motives are out of date. The specious Marxian theory of economic necessity can certainly be discounted. In modern times what hopes can be excited by the prospect of war? What is it, for example, that gets into the Germans? Here issue must again be taken with Dr. West.

It was not "we" nor "mankind" nor any universal human infirmity that caused the last three great European wars. Neither was it Hitler who instigated the most recent one. Never in history can a ruler more completely have expressed the temper and purpose of his people than did Hitler in 1941. It was the Germans who caused these wars. Why? The strange truth is that by 1941, when success, admittedly, had exalted their dearest anticipations, every German was fighting to win a little gang of slaves that he could have for his very own. In pursuit of this ideal he was prepared to live on one meal a day indefinitely. Such, in its fullest flowering, was the vision of the German *Weltanschauung*.

Because this aim was monstrous the peoples of the world outside Europe are now largely unable to believe that it existed. By contrast, on the Continent, it is too well understood even to merit discussion. It would be well if comprehension were more general, for only with recognition and acceptance can the menace of such behaviour be dissipated. The German aberration owes nothing to heredity. It is the result of conditioning. New contacts and a changed mental environment, if long enough continued, would effect a cure.

In other nations today impulses of genuine fear may be shaping the minds of men towards "preventive" aggression. No effort should be spared in the attempt to identify and allay such apprehensions. Whatever its origin, however, it is to be hoped that in future the remainder of the world will more readily accept evidence of aggressive intent. For the present it is unwise that Dr. West and Dr. Comfort should seek an end to well-tried loyalties. In doing so they must place in jeopardy the only foundations which as yet offer practical hope for the defence of freedom. In the recent words of Winston Churchill: "How easy it is to impair great unities and how hard to make them."

DANGER FROM THE NEWER INSECTICIDES

SIR,—I have read with interest your annotation of March 4, and the subsequent correspondence. As a layman, may I ask if, apart from any question of humanity, we are wise in using insecticides which, if so dangerous to man, must be death to small birds and the wild animals? Have they no value? Can we live in a desert?

Caterham, Surrey. E. E. RICHARDS.

PELVIC TUBERCULOSIS IN THE FEMALE

SIR,—Your account last week of a meeting of the Edinburgh Obstetrical Society recorded a high mortality in the surgical treatment of pelvic tuberculosis in the female, and ended with the statement that a controlled clinical investigation is urgently required into the effect on this disease of streptomycin and *p*-aminosalicylic acid. There is good reason to believe that an extended study of this problem will be arranged in the near future. In the meantime, we would report, for the encouragement of others, that of the last 6 women with tuberculous endometritis and salpingitis treated in this department with streptomycin alone, 5 have been apparently cured.

The diagnosis was made only when a positive culture from the endometrium was obtained, and apparent cure was assumed only when three consecutive biopsies at monthly intervals yielded negative cultures and no histological evidence of disease. It is too early to state with assurance that the cure is absolute.

In the last ten years, 49 women have been treated by us for pelvic tuberculosis. Prior to the use of streptomycin the only cures were obtained by radical surgery, using the same technique as we adopt for carcinoma of the corpus; 14 patients were treated in this way with no operative and no postoperative deaths and no fistulæ. If the encouraging results so far obtained with streptomycin continue, it may be possible in many cases to both cure the disease and preserve normally functioning organs.

ANTIGEN-ANTIBODY REACTIONS

SIR,—I was much interested in Dr. Stratton's article of Feb. 11.

The concept of non-specificity was suggested very early. A number of workers have urged me to use Rh-negative hapten as a "control": but I think that the conviction that hapten made from Rh-negative blood is inactive is based on a misconception. The term "Rh-negative" suggests that such blood lacks something; but, of course, thanks to a number of workers, including R. R. Race and R. A. Fisher, we know that this is not the case.

An individual who is Rh-negative (or Hr-positive) carries a factor in his blood which, in all probability, is very closely similar, biochemically speaking, to Rh. From the viewpoint of biochemistry, the difference between D and d may be not greater than the difference between glucose and fructose, or even *d*- and *l*-isomers.

I have made hapten from Rh-negative blood; and I have made other specific haptens from the various subtypes. These I have assayed very carefully. With an anti-D serum one obtains strong reactions with a D antigen, and weaker reactions with a C or an E or a cde antigen. This is just what I would expect. I would look for a situation such as is found, in relation to serological interactions, in the paratyphoid-enteritidis group. If a mutual polysaccharide can give us the test for a rickettsial infection with the use of proteus organisms (to cite another example), I would find it most astonishing if the Rh-negative hapten were to constitute a valid control. Specificity is a matter of biochemistry. If Dr. Stratton were to obtain inhibition of anti-A or anti-B serum with his hapten, then I would call it non-specific. But I do not think that the concept will hold within the Rh-Hr system.

INTRAMUSCULAR ADMINISTRATION OF VITAMIN E

SIR,—In the original reports on the use of vitamin E (α-tocopherol) in the treatment of certain cardiac conditions, arterial obliterative disease, and diabetes mellitus, I dealt almost exclusively with the oral method of administration. The reason for this is obvious, economy and comfort to the patient being not inconsiderable factors.

From time to time, however, one sees cases in which, because of dire need, one cannot wait from four to ten days for therapeutic effect. Cases of severe heart-failure, of diabetic, arteriosclerotic, or Buerger's gangrene, or of semicomatose states will demand immediate action, which can best be provided by intramuscular injection of α-tocopherol. In the past four years I have used this technique in some forty-five cases, mainly of severe heart-failure.

An 18-gauge needle of at least $1^3/_4$ in. is used. Because the oil is heavy a higher gauge will cause great difficulty both in aspiration and injection. The oil should not be heated to make it more manageable lest the tocopherol be inactivated. A 'Luer-lok' syringe helps to avert untimely separation of syringe and needle during injection. The material is injected deeply into the upper and outer quadrant of the buttock.

A reliable standard dosage is 300–400 international units daily for four or five days; but this dosage must be modified in the presence of certain conditions discussed below.

The first injection generally produces a dramatic change within twelve hours. In cases of extreme heart-failure excess fluid and transudates are rapidly eliminated by the kidneys and skin. Patients who are beyond middle age lose most of this fluid through the kidneys, probably because of atrophic changes in the sweat-glands; younger patients often sweat very profusely. The dosage on succeeding days may be regulated by the degree of compensation effected by the initial injection.

Great care must be exercised where any of the following conditions are observed:

Digitalis intoxication.—Through its synergistic action with digitalis bodies in protecting against the destruction of co-enzyme I,[1] α-tocopherol sensitises the myocardium to digitalis. For this reason the maintenance dose of digitalis given by mouth to patients receiving vitamin E is less than usual. Furthermore, the mobilisation of body-fluids, which is a part of the profuse diuresis, will greatly increase the amount of circulating digitalis bodies, as with any diuretic. Consequently, one must be careful not to give large doses of vitamin E by injection to patients who show any sign of digitalis intoxication.

Extensive renal damage.—The relatively sudden diuresis described above can be harmful where the kidney glomeruli are severely damaged. A case of rheumatic heart-disease with mitral stenosis in complete failure with massive pulmonary œdema, hepatomegaly, ascites, and well-marked dependent œdema was compensated in twenty-four hours by an injection of 400 international units; but after five days the blood non-protein nitrogen began to rise to alarming heights and the patient died in uræmia. Presumably there had been widespread renal rheumatic involvement which prevented the kidneys from handling the sudden excretory overload.

Prostatic obstruction.—In anticipating profound diuresis it is wise to ensure free drainage of the bladder where there has been any prostatic difficulty. An indwelling catheter will prevent any danger of undesirable back-pressure.

Diabetes mellitus.—Before using vitamin E by injection in a diabetic, one must bear in mind that pronounced hypoglycæmia will develop, reaching its maximum in about four hours.[2] One must therefore watch the blood-sugar very carefully in order to prevent severe hypoglycæmia, and it is usually best to reduce the dosage of insulin to allow some room for this effect.

Hyperthyroidism.—No patient with any evidence of thyroid overactivity should be given α-tocopherol. Some later investigators claim that in hypertensives vitamin E raises the blood-pressure; but in my opinion these "hypertensives" were probably cases of hyperthyroidism.

The results achieved are illustrated by the following case:

A 72-year-old man had dyspnœa and œdema of the ankles which for the past four months had become progressively more severe. Nocturnal dyspnœa had become so pronounced that for the last two weeks he had spent his nights in a chair.

The pulse was irregular, rate 108 per min.; blood-pressure 186/100 mm. Hg. Weight 157 lb. Chest: moist râles throughout both lung fields; pleural effusion over the lower third of the right lung. Heart: on percussion and fluoroscopy, enlarged about 2 in. to the left of the mid-clavicular line; mitral systolic murmur. Liver: tender and enlarged four finger-breadths below costal margin. Ankles: severe pitting œdema. Ocular fundi: well-marked arteriosclerotic silver-wire appearance with "nicking."

The patient was given 300 international units of vitamin E, in the form of 'Natopherol' acetate in oil (Abbott) by intramuscular injection and 0·1 mg. digitoxin as 'Purodigin' (Wyeth) orally for five days. In twelve hours the œdema of the ankles had disappeared; the fluid in the right pleural cavity had gone; the moist sounds in both lungs had almost completely vanished; and the liver was less than two finger-breadths enlarged. By the second day he was "compensated" and could lie flat in bed to sleep.

This patient had previously received no digitalis; and it does not seem possible that the effect noted could be due to the 0·1 mg. doses of digitoxin.

Thanks are extended to the Abbott Laboratories, of North Chicago, Illinois, and to the V.C.A. Laboratories, of Newark, N.J., for generous supplies of injectable α-tocopherol.

London, Ontario. ARTHUR VOGELSANG.

DEOXYCORTONE WITH ASCORBIC ACID IN MENTAL DISORDER

SIR,—With regard to the article of March 25 by Dr. Cranswick and Dr. Hall, it may be of some interest to point out that since 1949 we have been carrying out research into adrenal cortical reactions to various stimuli with the blood ascorbic-acid at different levels. These studies have been made both in animals and man, either healthy or experimentally or naturally suffering from various conditions which could be grouped with the "adaptation syndromes"—among them, psychoneurosis and psychosis. We have published preliminary results from these researches, including data on the blood and on urinary steroid metabolites.[3]

These results cover over 40 cases of rheumatoid arthritis, allergic stat [illegible] conditions, submitted to stimuli [illegible] l Wassén's[4] technique. The results are therapeutically favourable, and interesting for the hæmatological and urinary findings. In particular, one of us[5] has pointed out some really remarkable effects in 23 neuropsychiatric cases; these patients were chiefly depressives, with hæmatological and urinary findings comparable to those recorded by Cranswick and Hall.

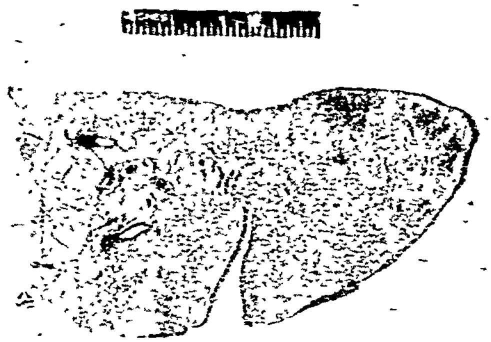
ESSENTIAL BROWN INDURATION OF THE LUNGS

SIR,—Since the publication of an article with the above title,[1] I have had some interesting letters from American and English pædiatricians, who ask how I attribute the entity to a neurovascular disorder.

The illustration is of a thin slice of affected lung cut with a bacon-slicing machine. It shows well the uniform and gross consolidation, which is due to massive diapedesis of red blood-corpuscles into the air-sacs. (The condition illustrated is universal in the lung tissue.) A few cystic air-sacs are seen at the apex of the lung. These, relative to the other pathological findings, are inconspicuous.

The histological picture of the lung corresponds to the edge of a pulmonary infarct where the capillaries are dilated and stuffed with blood and there is massive diapedesis but the walls of the air-sacs are still viable.



In other words, this corresponds to severe but incomplete anoxæmia. The induration (interstitial fibrosis, thickening of basement membranes) of the alveolar walls is consistent with chronic anoxæmia. One could conceive of such a condition being produced by spasm of the pulmonary artery: while an intermittent and variable degree of spasm would tally with the clinical picture of variable, intermittent bouts of severe anoxic anoxæmia. The pathological picture is somewhat similar to renal lesions in eclampsia which can also be attributed to arterial spasm.

A hypothesis of arterial spasm, however, does not explain the deficiency of elastica in the alveolar walls. In the absence of any special knowledge of the problem of elastica, I would also attribute this deficiency to chronic anoxæmia. It is interesting to note that, in addition to the pathological lesions confined to the pulmonary capillaries, the other pulmonary lesions (fibrosis, elastica deficiency) are confined to the air-sacs. The septal and peribronchial connective-tissue framework is not altered. To me this also points to a prime vascular disease; and, since it is universal, one should work back to a prime abnormality in the pulmonary artery. Investigation of this disease in life, with a hypothesis of pulmonary arterial spasm in mind, should help to unravel the mystery.

Regina General Hospital, Saskatchewan. N. G. B. McLETCHIE Director of Laboratories.

AGAROL

SIR,—Mr. Bastow's enthusiasm for exploding myths has run away with him: the prices he quotes as paid to the pharmacist for both Agarol and the *N.F.* substitute are wrong. He has omitted the dispensing fees (8*d.* in each case) and the 1½*d.* for the bottle, which is added to his charge for the *N.F.* emulsion, but not for agarol.

Mr. Bastow is quite right that the public pay for research—as they pay for the money that he (if a retail pharmacist) has invested in his business, as they pay for a successful doctor's training. If Mr. Bastow belongs to the school that would prefer to pay for research out of taxes, he might reflect that the public then pays for *all* research; the manufacturer can *only* recoup himself when research has yielded valuable results.

William R. Warner & Co. Ltd., London, W.4. ELIOT WARBURTON.

PULMONARY BILHARZIASIS AND LOEFFLER'S SYNDROME

SIR,—In his letter of Jan. 28, Dr. Malhotra reported four cases of filariasis with diffuse mottling of the lung fields and eosinophilia. Dr. Ball referred to this communication in his letter of Feb. 25, and added pulmonary bilharziasis to the list of diseases [1] in which pulmonary infiltration and eosinophilia are associated.

I wish to express a different view and incidentally to settle the question of priority of the description of chronic pulmonary bilharziasis with eosinophilia.[2–4]

Actually, I was the first to describe, in 1935, the clinical features and radiological appearances of this entity [5]; and a year later I published a paper with the first reproductions of radiographs of the disease,[6] which unfortunately were not clear in the earlier article. In a subsequent report [7] a classification of the radiographic appearances was proposed. Whilst these findings were presumably due in the majority of cases to infestation with *Schistosoma hæmatobium*, analogous lung involvement was reported in intestinal bilharziasis (*Schistosoma mansoni*) [8] and in bilharzial bronchial asthma.[9] The entire findings were finally surveyed in a concluding paper.[10] referred to by Erfan.[2 3]

These earlier reports on a clinical finding now common since once one has become "lung-conscient" in bilharziasis, were only partly confirmed some years ago. This is evident from an article on bilharzial heart-disease in Egypt,[11] where it is stated:

> "Mainzer (1938) has described the X-ray appearance of miliary infiltration of the lung fields in pulmonary bilharziasis, but . . . these miliary shadows have only been observed . . . during the course of antimony treatment, and are regarded as due to an allergic action around the ova."

11. Bedford, D. E., Aidaros, S. M., Girgis, B. *Brit. Heart J.* 1948, 8, 87.

In my original cases, however, these miliary infiltrations, as well as more extensive bilharzial lung foci, were always present before specific treatment, since previously they had almost all been regarded as tuberculous. The same was true in the case of a British consular official, formerly resident in a bilharzia-infested district of Brazil; his illness was diagnosed as miliary tuberculosis in Switzerland and took a favourable course contrary to every expectation (personal communication from Prof. A. Gigon, 1936).

As I pointed out in a short monograph,[12] Loeffler's syndrome should strictly be distinguished from the diffuse pulmonary infiltrations occurring in tropical eosinophilia [13] and pulmonary bilharziasis; the same arguments are valid with reference to pulmonary filariasis with eosinophilia. In the latter conditions the lung is mottled by innumerable small foci. In Loeffler's syndrome, as conceived by its author [14] there is one or more larger foci, one not infrequently developing after the disappearance of another; the syndrome takes usually (but not always) a short, self-limiting course. On the contrary, the lung infiltrations in pulmonary bilharziasis, tropical eosinophilia (ascariasis of the lung), and pulmonary filariasis run a completely different course which depends on the specific nature and treatment of the basic illness. Therefore, the two groups of pathological entities (since Loeffler's syndrome also is in all probability not uniform in its origin) have in common only that there is "something in the lung" and blood eosinophilia; otherwise they are completely different ætiologically, morphologically, and clinically. For these reasons it would be unwise, and it would hamper further progress, to place under a single heading such widely differing disorders.

Anglo-Swiss Hospital, Alexandria, Egypt. FR. MAINZER.

STREPTOKINASE: A WARNING

SIR,—In your leading article of April 1, on New Uses for Streptococcal Enzymes, you indicate that streptokinase may be valuable in aiding the removal of different types of effusions from body cavities, and also in cleansing infected surfaces.

My colleagues and I have been asked more than once recently about the application of this product for the prevention of postoperative adhesions. We believe that the intraperitoneal injection of streptokinase for this purpose may not be devoid of risk. The formation of fibrin clot is the first stage in the healing of a wound (e.g., an incision into a viscus); any enzyme which dissolves the fibrin clot seems likely to delay healing, possibly leading to leakage from stomach or intestine and causing peritonitis. I suggest that the problem should be approached cautiously.

Wellcome Research Laboratories,
Beckenham, Kent. H. J. PARISH.

THE LATE SIR NORMAN HAWORTH

SIR,—In your short notice of the death of my colleague, Sir Norman Haworth, you draw attention to his work with E. L. Hurst, which established the formula of vitamin C and then add the remark "which later made its synthesis and large-scale production possible." The addition, I think, does not make it quite clear that these workers actually achieved this synthesis, although they were forestalled, by three weeks, by Reichstein, of Basle, who synthesised the vitamin by a different method. This was the first vitamin ever to be synthesised and Haworth gave it its name of "ascorbic acid."

In collaboration with his colleague, Prof. M. Stacey, Haworth made two other contributions which are of great importance in medicine. The first was the elucidation of the chemical processes involved in certain immunological procedures, and the second their discovery of a sugar product, dextran, and their suggestion that it could be used as a substitute for blood-plasma.

The high opinion in which Haworth was held by his colleagues is shown by the tribute paid to him by Prof. M. L. Oliphant at a memorial service, in the course of which he said:

> "There are few universities which in this century have nurtured men of Haworth's calibre and Birmingham will be proud for all time that he worked here. It is certain that he was the greatest scientist our university has harboured and this is a statement of great significance in a university with our record of achievement."

University of Birmingham. LEONARD G. PARSONS.

GENERAL PRACTICE TODAY

SIR,—The Collings report has already called forth both friendly and hostile comment. The *British Medical Journal* is particularly trenchant in its criticism. "What we must ask ourselves" it states, "is whether Dr. Collings's limited experience of only 55 general practices is a true reflection of the whole of general practice. The answer is obviously 'No.' And it is most regrettable that he has attempted to generalise from so few particulars."

The truth of the matter is that 55 practices of the types selected provide a very fair cross-section, surely comparable with that provided by a Gallup poll. Moreover, if we have no political or sectarian axe to grind, are we not all aware that general practice today is sick at heart? Far from the report being tendentious and one-sided, it does, in effect, offer a springboard from which an early campaign may be launched to provide this countr[illegible]dical service worthy of its great [illegible] Furthermore, it entirely justifies the fears so many of us have felt, and from time to time dared to express, that all could not be well technically, ethically, clinically, or indeed in any other way, in hundreds of practices boasting full lists and maximum incomes.

To be exact, our present system has, by its encouragement of large and competitive panels, reduced the status of many practitioners to that of the shopkeeper, and their potentialities for exercising a proper professional discipline and skill in some cases to precisely nil. Chapter and verse for these heart-rending conclusions have been given at such length, so frequently, and in so many places (not only in the Collings report) that further elaboration of the theme is redundant.

We are, then, faced with a tragic fait-accompli. As Dr. Collings has been at pains to emphasise, this state of affairs is not the direct outcome of the National Health Service Act; but he does point out that "extension of National Health Insurance" has so increased the load as to cause serious strain or near-breakdown. What nonsense it is to expect any man to cope effectively with 120 items of service, or even half that number, in any one day.

The precipitate action of the Minister in launching the service, the surrender of the profession's official representatives to what appeared to be (but was not in fact) superior force, and, perhaps above all, the pathetic apathy shown by the rank and file since July, 1948, have all contributed to the present tragedy.

In considering the therapeutic measures necessary to restore health to the general medical service, a far more heroic method will be required than that suggested by Dr. Collings. The "deliberative task" of "defining the future province and function of general practice" must be undertaken by a body with the highest powers of taking and sifting evidence, and one whose recommendations will receive immediate attention at top level. Such a body should, in fact, be no less than a

---

12. Mainzer, F. Visceral Bilharziasis. To be published.
13. Weingarten, R. J. *Lancet*, 1943, i, 103; *Ind. Phys.* 1943, 2, 369.

Royal Commission—not a departmental committee—the membership of which should include a fair proportion of general practitioners.

Our official representatives and negotiating bodies have not in the past done a great deal to warrant any real faith in their abilities to express the sentiments of the "ordinary" doctor. It may be that it is not too late to hope for a change of heart in the hierarchy of the B.M.A. Should this be true, the democratic means of enforcing action in accordance with our opinions exist and should be used fully. The B.M.A. is not, however, the only means of expression. Much can also be effected by resolute approach through local medical committees.

The main points which require the earliest possible *attention, are these:*

1. The widening gap between hospital services and general practice must be closed. For this to be effective the good will of professional colleagues in the consultant and specialist ranks is essential—its existence at present is somewhat doubtful. The provision of G.P. beds in hospitals, appointments to part-time clinical posts, and a wider recognition, especially by more junior hospital officers, that general practitioners, given the opportunity, can be good doctors and helpful colleagues, would all go far to improve clinical standards and unite the profession.
2. Some means must be found to reduce the maximum panel list to 2500 patients while retaining a reasonably high rate of emolument. Even this number is far higher than it should be for the maintenance of a truly high standard. The optimum figure should probably be in the neighbourhood of 1500. That this requirement must incur great increases in cost is unfortunately true. Further, we may expect little consideration from a hard-pressed Treasury. But to build an efficient G.P. service, retrenchment elsewhere is justifiable; therefore reduce the dental service really drastically, allowing only grants-in-aid, and cut out provision of free spectacles and surgical appliances other than those absolutely essential. Watch administrative costs and expense allowances. Enforce the charge on all prescriptions. And let it be remembered that less crowded G.P. consulting-rooms will relieve the hospitals immeasurably.
3. Health centres and group practice must be developed as a top priority, if necessary with the use and adaptation of existing buildings. If liaison with the hospitals is close enough, here is a quick solution of the overcrowded out-patient-department problem. To attain this end, education of the general practitioners themselves will be essential; the doctor was ever conservative and suspicious in his outlook and concepts. As a corollary, responsibility for the provision of health centres should be removed immediately from local authorities, which are quite out of touch with the problem, and vested in the executive councils, perhaps with representatives from hospital committees coöpted.
4. There must be an immediate raising of all restrictions on practice, in that any doctor, provided that he is professionally and morally acceptable, should be accorded admission to an executive-council list where and as he wishes. As a profession, we have made a great noise on the subject of improper direction. We are now more to blame than the layman so far as the "closed shop" issue is concerned.
5. The public must be made more extensively aware of the poor deal with which they have been fobbed off. Members of Parliament, whatever their party, must be primed with the true facts, and especially our medical Members must recognise their responsibilities. (In parenthesis, how sadly few they are!)

Dr. Collings has raised a standard to which we must now rally and which may well serve to unite our apathetic and discouraged profession. The truths he has served up are no doubt unpalatable to many, and in certain circles every effort will be made to belittle his contribution to a solution of this most important social problem. British medicine has had a high reputation, much of which has already been dissipated. That reputation can and must be restored.

Folkestone. G. J. V. CROSBY.

SIR,—Dr. Collings's article contains a useful picture of practice in industrial areas, presumably since the start of the Health Act. But on internal evidence I should be chary of accepting the accuracy of his descriptions.

It is well known that the Act forbids dispensing by medical practitioners in towns where a chemist is available. Yet on p. 557 he says: "Where dispensing is undertaken a third room may be set aside for this purpose." Again on p. 562 (industrial practice example no. 1, with no private patients) the surgery contained a dispensary and a lady dispenser was employed, who also acted as a telephonist and receptionist. Again, on p. 563 (industrial practice example no. 2, in a densely populated area) "a kind of cupboard . . . served as a dispensary (the practice had always done its own dispensing.) . . . Large stock bottles were standing all over the place." The number of attendances enumerated for this practice suggests that each of the 20,000 patients on the list averaged 10 attendances per annum—a figure far in excess of the accepted experience.

Perhaps these are "merely corroborative details to add an air of verisimilitude to an otherwise bald and unconvincing narrative."

Finchampstead, Wokingham, Berks. E. BILLING.

SIR,—In his sweeping condemnation of general practice in Britain Dr. Collings places special emphasis on the poor equipment and premises used by the general practitioner. While he mentions the abandonment of the health-centre scheme, he does not, I think, give sufficient consideration to the disastrous effect on general practice which that abandonment exercised.

Dr. Collings, it is true, mentions that "Many practitioners now regard the promise of health centres as a political trick, designed to gain their support at the time of the negotiations, or at least as an unfulfilled promise whose fulfilment is now unlikely." He does not, I think, realise how great was the disillusionment and resentment felt especially by the young doctors who had been promised, in section 21, lavish equipment and specially designed premises, and, counting upon this promise, ceased to trouble themselves about these two items.

The manner in which the Minister broke the promises contained in section 21 of the Act aggravated the anger of the profession. The undertaking was broken by the unobtrusive method of a circular (no. 3, Jan. 14, 1948)—and it is to be noted that circulars do not require, as do regulations, to be laid before Parliament. The Minister secured the virtual repeal of section 21, and this exercise of dictatorial power constitutes a new advance on the road to totalitarianism. I believe it to be without precedent that it should be within the power of a Minister, without reference to Parliament, and with no authority other than his own fiat, to annul a section of an Act of Parliament already on the statute-book, described by the Minister himself as "a key feature in the reconstruction of the country's health services."

The non-provision of the promised health centres has roused strong protests from every part of the House, and it is significant that the trade unions, through the T.U.C., are now demanding the immediate provision of 100 health centres. A recent Parliamentary answer (*Hansard*, March 23, 1950) revealed that since the passage of the Act in 1946, as regards health centres, "one new building is under construction; one other new building and one adaptation have been approved." The provision of health centres is obviously relegated to the Greek calends.

The Athenæum, London, S.W.1. E. GRAHAM-LITTLE.

SIR,—Whatever its merits as a quantitative survey, as a qualitative survey, the Collings report has not so far been effectively challenged. This being so, it deserves very serious discussion among medical students, many of whom will be influenced by its conclusion.

In my original cases, however, these miliary infiltrations, as well as more extensive bilharzial lung foci, were always present before specific treatment, since previously they had almost all been regarded as tuberculous. The same was true in the case of a British consular official, formerly resident in a bilharzia-infested district of Brazil; his illness was diagnosed as miliary tuberculosis in Switzerland and took a favourable course contrary to every expectation (personal communication from Prof. A. Gigon, 1936).

As I pointed out in a short monograph,[12] Loeffler's syndrome should strictly be distinguished from the diffuse pulmonary infiltrations occurring in tropical eosinophilia [13] and pulmonary bilharziasis; the same arguments are valid with reference to pulmonary filariasis with eosinophilia. In the latter conditions the lung is mottled by innumerable small foci. In Loeffler's syndrome, as conceived by its author [14] there is one or more larger foci, one not infrequently developing after the disappearance of another; the syndrome takes usually (but not always) a short, self-limiting course. On the contrary, the lung infiltrations in pulmonary bilharziasis, tropical eosinophilia (ascariasis of the lung), and pulmonary filariasis run a completely different course which depends on the specific nature and treatment of the basic illness. Therefore, the two groups of [illegible]ies (since Loeffler's syndrome also is [illegible] not uniform in its origin) have in common only that there is "something in the lung" and blood eosinophilia; otherwise they are completely different ætiologically, morphologically, and clinically. For these reasons it would be unwise, and it would hamper further progress, to place under a single heading such widely differing disorders.

Anglo-Swiss Hospital, Alexandria, Egypt. FR. MAINZER.

STREPTOKINASE: A WARNING

SIR,—In your leading article of April 1, on New Uses for Streptococcal Enzymes, you indicate that streptokinase may be valuable in aiding the removal of different types of effusions from body cavities, and also in cleansing infected surfaces.

My colleagues and I have been asked more than once recently about the application of this product for the prevention of postoperative adhesions. We believe that the intraperitoneal injection of streptokinase for this purpose may not be devoid of risk. The formation of fibrin clot is the first stage in the healing of a wound (e.g., an incision into a viscus); any enzyme which dissolves the fibrin clot seems likely to delay healing, possibly leading to leakage from stomach or intestine and causing peritonitis. I suggest that the problem should be approached cautiously.

Wellcome Research Laboratories,
Beckenham, Kent.
H. J. PARISH.

THE LATE SIR NORMAN HAWORTH

SIR,—In your short notice of the death of my colleague, Sir Norman Haworth, you draw attention to his work with E. L. Hurst, which established the formula of vitamin C and then add the remark "which later made its synthesis and large-scale production possible." The addition, I think, does not make it quite clear that these workers actually achieved this synthesis, although they were forestalled, by three weeks, by Reichstein, of Basle, who synthesised the vitamin by a different method. This was the first vitamin ever to be synthesised and Haworth gave it its name of "ascorbic acid."

In collaboration with his colleague, Prof. M. Stacey, Haworth made two other contributions which are of great importance in medicine. The first was the elucidation of the chemical processes involved in certain immunological procedures, and the second their discovery of a sugar product, dextran, and their suggestion that it could be used as a substitute for blood-plasma.

The high opinion in which Haworth was held by his colleagues is shown by the tribute paid to him by Prof. M. L. Oliphant at a memorial service, in the course of which he said:

> "There are few universities which in this century have nurtured men of Haworth's calibre and Birmingham will be proud for all time that he worked here. It is certain that he was the greatest scientist our university has harboured and this is a statement of great significance in a university with our record of achievement."

University of Birmingham. LEONARD G. PARSONS.

GENERAL PRACTICE TODAY

SIR,—The Collings report has already called forth both friendly and hostile comment. The *British Medical Journal* is particularly trenchant in its criticism. "What we must ask ourselves" it states, "is whether Dr. Collings's limited experience of only 55 general practices is a true reflection of the whole of general practice. The answer is obviously 'No.' And it is most regrettable that he has attempted to generalise from so few particulars."

The truth of the matter is that 55 practices of the types selected provide a very fair cross-section, surely comparable with that provided by a Gallup poll. Moreover, if we have no political or sectarian axe to grind, are we not all aware that general practice today is sick at heart? Far from the report being tendentious and one-sided, it does, in effect, offer a springboard from which an early campaign may be launched to provide this country with a general medical service worthy of its great professional tradition. Furthermore, it entirely justifies the fears so many of us have felt, and from time to time dared to express, that all could not be well technically, ethically, clinically, or indeed in any other way, in hundreds of practices boasting full lists and maximum incomes.

To be exact, our present system has, by its encouragement of large and competitive panels, reduced the status of many practitioners to that of the shopkeeper, and their potentialities for exercising a proper professional discipline and skill in some cases to precisely nil. Chapter and verse for these heart-rending conclusions have been given at such length, so frequently, and in so many places (not only in the Collings report) that further elaboration of the theme is redundant.

We are, then, faced with a tragic fait-accompli. As Dr. Collings has been at pains to emphasise, this state of affairs is not the direct outcome of the National Health Service Act; but he does point out that "extension of National Health Insurance" has so increased the load as to cause serious strain or near-breakdown. What nonsense it is to expect any man to cope effectively with 120 items of service, or even half that number, in any one day.

The precipitate action of the Minister in launching the service, the surrender of the profession's official representatives to what appeared to be (but was not in fact) superior force, and, perhaps above all, the pathetic apathy shown by the rank and file since July, 1948, have all contributed to the present tragedy.

In considering the therapeutic measures necessary to restore health to the general medical service, a far more heroic method will be required than that suggested by Dr. Collings. The "deliberative task" of "defining the future province and function of general practice" must be undertaken by a body with the highest powers of taking and sifting evidence, and one whose recommendations will receive immediate attention at top level. Such a body should, in fact, be no less than a

Royal Commission—not a departmental committee—the membership of which should include a fair proportion of general practitioners.

Our official representatives and negotiating bodies have not in the past done a great deal to warrant any real faith in their abilities to express the sentiments of the "ordinary" doctor. It may be that it is not too late to hope for a change of heart in the hierarchy of the B.M.A. Should this be true, the democratic means of enforcing action in accordance with our opinions exist and should be used fully. The B.M.A. is not, however, the only means of expression. Much can also be effected by resolute approach through local medical committees.

The main points which require the earliest possible attention, are these:

1. The widening gap between hospital services and general practice must be closed. For this to be effective the good will of professional colleagues in the consultant and specialist ranks is essential—its existence at present is somewhat doubtful. The provision of G.P. beds in hospitals, appointments to part-time clinical posts, and a wider recognition, especially by more junior hospital officers, that general practitioners, given the opportunity, can be good doctors and helpful colleagues, would all go far to improve clinical standards and unite the profession.

2. Some means must be found to reduce the maximum panel list to 2500 patients while retaining a reasonably high rate of emolument. Even this number is far higher than it should be for the maintenance of a truly high standard. The optimum figure should probably be in the neighbourhood of 1500. That this requirement must incur great increases in cost is unfortunately true. Further, we may expect little consideration from a hard-pressed Treasury. But to build an efficient G.P. service, retrenchment elsewhere is justifiable; therefore reduce the dental service really drastically, allowing only grants-in-aid, and cut out provision of free spectacles and surgical appliances other than those absolutely essential. Watch administrative costs and expense allowances. Enforce the charge on all prescriptions. And let it be remembered that less crowded G.P. consulting-rooms will relieve the hospitals immeasurably.

3. Health centres and group practice must be developed as a top priority, if necessary with the use and adaptation of existing buildings. If liaison with the hospitals is close enough, here is a quick solution of the overcrowded out-patient-department problem. To attain this end, education of the general practitioners themselves will be essential; the doctor was ever conservative and suspicious in his outlook and concepts. As a corollary, responsibility for the provision of health centres should be removed immediately from local authorities, which are quite out of touch with the problem, and vested in the executive councils, perhaps with representatives from hospital committees coöpted.

4. There must be an immediate raising of all restrictions on practice, in that any doctor, provided that he is professionally and morally acceptable, should be accorded admission to an executive-council list where and as he wishes. As a profession, we have made a great noise on the subject of improper direction. We are now more to blame than the layman so far as the "closed shop" issue is concerned.

5. The public must be made more extensively aware of the poor deal with which they have been fobbed off. Members of Parliament, whatever their party, must be primed with the true facts, and especially our medical Members must recognise their responsibilities. (In parenthesis, how sadly few they are!)

Dr. Collings has raised a standard to which we must now rally and which may well serve to unite our apathetic and discouraged profession. The truths he has served up are no doubt unpalatable to many, and in certain circles every effort will be made to belittle his contribution to a solution of this most important social problem. British medicine has had a high reputation, much of which has already been dissipated. That reputation can and must be restored.
